**FIGURE 83-16** Relationships of levels of gene expression, reflected as the activity of single homologous alleles (left) and the sum of the activities of the two homologous alleles (right). The dashed line represents the minimal sum of allelic activity required to prevent autosomal recessive (A), autosomal dominant (B), and dominant-negative (C) disorders. (From Phillips, J. A. III. *Dominant-Negative Diabetes Insipidus and Other Endocrinopathies*. J. Clin. Invest. **2003**, 112, 1641–1643.)

18 genes which demonstrated the dominant-negative phenomenon and were instances of hormone deficiency (128).

In families with ADNDI, genetic testing for AVP mutations may be helpful in pre-symptomatic patients and in those patients with equivocal water deprivation testing (129).

### 83.3.2 Other Forms of Familial Neurohypophyseal DI

In the 1940s, Forssman et al. described a large kindred with apparent X-linked familial NDI (FNDI). Patients had partial response to vasopressin. Subsequently, however, the same kindred was relocated and found to have a form of nephrogenic DI with a

confirmed AVPR2 gene mutation (130). In 1996, however, Habiby et al. described a kindred with apparent X-linked FNDI with linkage to Xq28. Mutations in either AVPR2 or AVP were not found and the etiology remains unknown.

Two kindreds with autosomal recessive FNDI have been reported. Each kindred (one an Arab family living in Texas, one a Palestinian family) had the same P26L mutation and microsatellite analysis suggested a founder effect. The presentation was essentially the same as in ADNDI, with the exception that the patients in the second kindred presented in the first few weeks of life. All responded well to desmopressin therapy. The mutant AVP is secreted but has a 30-fold decrease in V2 receptor binding and a 10-fold decrease in the ability to stimulate adenylate cyclase (131).

### 83.3.3 Wolfram Syndrome

This autosomal recessive syndrome is also known as the DIDMOAD syndrome and consists of *DI*, Diabetes Mellitus, Optic Atrophy, and neurosensory Deafness (OMIM 222300; Table 83-1). The diabetes in Wolfram syndrome (WFS) is caused by degeneration of the insulin producing cells of the pancreas and is a constant feature of the syndrome. Functionally, the diabetes is similar to Type 1 diabetes, but there is no autoimmunity and the diabetes tends to be milder with less tendency toward ketoacidosis. Optic atrophy is typically the next sign to appear (occurs in 100% of patients), and may be present at the time of diabetes diagnosis. The optic atrophy is primary and it is characterized by white discs and, in some instances, peripheral retinal pigmentation. Bilateral neurosensory deafness is an integral component of the WFS and occurs in about 60% of patients; it begins as a high-frequency hearing loss and may remain quite mild. Hearing loss may not be suspected until audiograms are performed. Neurohypophyseal DI occurs in more than one-third of patients with this syndrome (132). Several families have been reported in which several members have the full-blown syndrome, whereas others have diabetes mellitus and optic atrophy without DI. AVP deficiency has been documented in affected patients following a hyperosmolar stimulus; normal free water resorption resumes following DDAVP administration. Postmortem examination of two siblings with this syndrome revealed degeneration of the hypothalamic nuclei, more severe in the paraventricular than supraoptic nuclei, and atrophy of the posterior lobe of the pituitary, adrenal cortex, pons, and substantia nigra.

A number of other associated abnormalities have been described in certain families, including ataxia, autonomic dysfunction with a neurogenic bladder, sideroblastic anemia, and hyper alaninuria. The progression over time of simple optic atrophy and diabetes mellitus to full-blown WFS with neurosensory hearing loss, atonic bladder, and ataxia in the patient appears to be due to the pleiotropic effects of a single mutant gene and represents one distinct syndrome (132).

WFS has been linked to 4p16. The gene, *WFS1* (OMIM 606201) has been identified and a variety of mutations have been described in Wolfram patients (133). *WFS1* codes for a novel transmembrane protein called wolframin, an endoglycosidase H-sensitive glycoprotein, which localizes primarily to the ER of a variety of neurons (hippocampus CA1, amygdaloid areas, or olfactory tubercle), inner ear cells, and pancreatic beta cells (134–136). In the ER, wolframin helps regulate calcium homeostasis and the unfolded protein response (137–139). Yamada et al. showed that wolframin deficiency increases ER stress resulting in eventual apoptosis of pancreatic beta cells (140). Khanim et al. identified *WFS1* mutations in 90% of the patients they studied. Most were compound heterozygotes with private mutations distributed

throughout the gene with no obvious hotspots (135). Smith et al. found that most causative changes identified in the *WFS1* gene occurred in exon 8 (141). Giuliano et al. screened 19 patients with WFS and 36 relatives from 17 French families for mutations in the *WFS1* gene (142). *WFS1* mutations were identified on both alleles in 16/19 (84%) patients and on one allele of three patients, showing that *WFS1* is the major gene involved in WFS in the French population. Genotype–phenotype correlations suggested that the presence of inactivating mutations on both alleles may be associated with an early onset of diabetes mellitus.

A second autosomal recessive form of WFS (*WFS2*, OMIM 604928) with linkage to 4q22–q24 has been established in several families (143). Amr et al. identified a single homozygous mutation in the zinc finger protein, CDGSH iron sulfur domain protein (*CISD2*, OMIM 611507). *CISD2* is expressed in brain and pancreas and localizes to the ER, where it also appears to regulate calcium homeostasis (144). *CISD2* null mice have a phenotype of premature aging, neurologic deterioration, and glucose intolerance consistent with some features of WFS (145).

Rotig et al. suggested that some cases of the syndrome of early-onset diabetes mellitus, optic atrophy, and deafness may have their basis in a mitochondrial mutation. They described a patient with this disorder in association with a 7.6-kb heteroplasmic deletion of mtDNA. Pilz et al. described a 19-year-old male with long-standing diabetes mellitus, optic atrophy, grand mal seizures, and unilateral sensorineural hearing loss who had the most common mitochondrial DNA mutation associated with Leber's hereditary optic neuropathy, which was inherited from his mother. They suggested that the DIDMOAD phenotype is a mitochondrial disorder in some cases and is likely to have a heterogeneous etiology. *CISD2* null mice have mitochondrial dysfunction and degeneration suggesting that mitochondrial dysfunction may be a final common pathway for both forms of WFS as well as other similar syndromes. Barrett et al. investigated a cohort of 50 WFS patients for evidence of a distinct mitochondrial haplotype and mitochondrial DNA rearrangements and found no evidence supporting a role for mtDNA in WFS (146).

## 83.4 GENETIC TESTING

Tests for many of the genetic disorders described are available either commercially or on a research basis. For up-to-date information on availability of testing for specific disorders, consult the GeneTests website (<http://www.geneclinics.org>).

This article is a revision of the previous edition article by Delbert A Fisher and Annette Grueters, volume 2, pp 1932–1950, © 2007, Elsevier Ltd.

The codes in parenthesis will refer to OMIM database (<http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed>; search OMIM).

### 84.1 INTRODUCTION

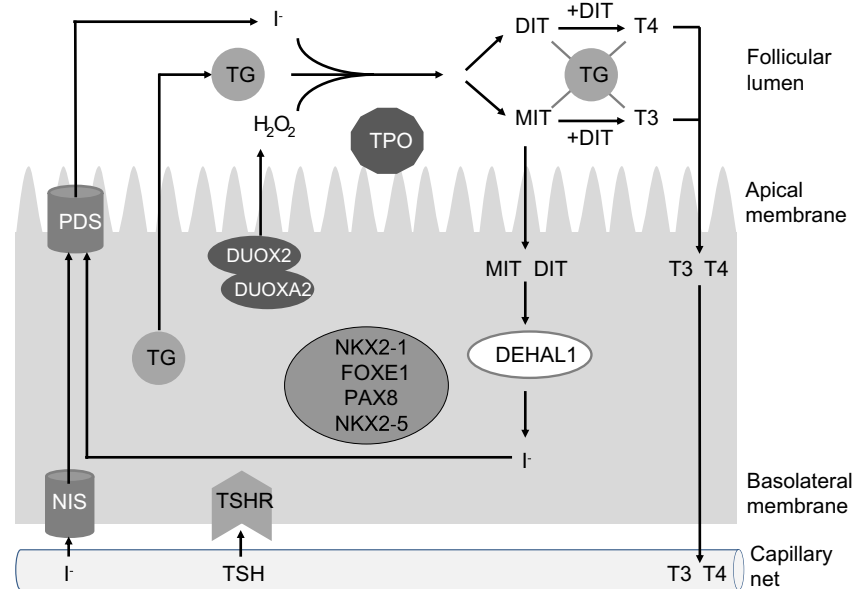

The mammalian thyroid gland consists of two endocrine cell types: (1) Thyroid follicular cells represent the large majority of endocrine cells of the thyroid. They form the monolayered spherical functional units of the mature thyroid tissue, the thyroid follicles and are responsible for thyroid hormone synthesis, storage and secretion. (2) Parafollicular C-cells represent less than 1% of cells in the human and produce calcitonin, a hormone involved in calcium homeostasis. C-cells are scattered as single cells or small-cell groups between the thyroid follicles and the dense capillary net in the thyroid interstitium (1,2).

The mammalian thyroid follicular precursor cells derive from the foregut endoderm and form the median anlage of the thyroid while C-cells are of neuroectodermal origin and are localized within the paired ultimobranchial bodies of the caudal pharyngeal pouches. After a migratory process, the median anlage fusions with the paired ultimobranchial bodies at the definitive pretracheal position. Thyroid development is accomplished with the onset of thyroid hormone synthesis at the end of the first trimester in the human embryo (2–5). Abnormal thyroid gland development or thyroid dysgenesis is the most common cause of permanent thyroidal congenital hypothyroidism in the human in iodine sufficient areas of the world.

The thyroid hormones are thyroxine (tetraiodothyronine, T<sub>4</sub>) and triiodothyronine (T<sub>3</sub>). These iodothyronines

are synthesized by fixation of four respectively three iodide atoms on thyronine residues resulting from condensation of two tyrosine amino acids. The only limiting substrate of thyroid hormone synthesis is iodide. Iodine deficiency remains worldwide still the most important reason for hypothyroidism. Thyroid hormone synthesis is characterized by several consecutive steps: (1) iodide uptake and concentration in the thyroid follicular cells, (2) thyroglobulin (TG) synthesis, (3) organification of iodide, and (4) iodotyrosine deiodination/iodide recycling. Inborn errors of thyroid hormone synthesis, called thyroid dysmorphogenesis, occur at any step of thyroid hormone synthesis and usually cause familial goitrous congenital hypothyroidism (6–8).

The most important factors controlling thyroid hormone synthesis are iodine availability and the hypothalamic–pituitary thyroid axis. Hypothalamic thyrotropin-releasing hormone (TRH) regulates pituitary thyrotroph synthesis and secretion of thyroid-stimulating hormone/thyrotropin (TSH). The activity of the hypothalamic–pituitary thyroid axis is under control of a negative feedback mechanism of circulating thyroid hormones. Secreted and circulating TSH binds to the TSH receptor (TSHR) localized at the basolateral membrane of the thyroid follicular cells. Receptor binding activates virtually every step in thyroid hormone synthesis and release mediated through the membrane-bound adenylate cyclase-cAMP second messenger system. In summary, TSH stimulates iodine uptake, TG synthesis, organification, stored TG endocytosis and thyroid hormone secretion (2,7–10). Developmental defects of the pituitary gland as well as inborn errors of the TRH

**FIGURE 84-1** Key Steps of Thyroid Hormone Synthesis. Thyroid hormone synthesis takes place at the apical membrane of the thyrocyte within the extracellular follicular lumen. Substrates for thyroid hormone synthesis are the amino acid tyrosine (not represented), iodide ( $I^-$ ), the glycoprotein TG and hydrogen peroxide ( $H_2O_2$ ). Iodide is incorporated into TG to form monoiodotyrosine (MIT) and diiodotyrosine (DIT) after oxidation and covalent binding to tyrosyl residues of the TG molecule. In a second step, thyroid hormones are formed by coupling of MIT and DIT to T3, or of two DITs to T4 or thyroxine. Four different mechanisms are involved in thyroid hormone synthesis. (1) Active  $I^-$  uptake from the bloodstream at the basolateral membrane by the sodium/iodide symporter (NIS, encoded by the *SCL5A5* gene) and  $I^-$  release into the follicular lumen at the apical membrane by pendrin (PDS, encoded by the *SCL26A4* gene). (2) TG synthesis and secretion into the follicle. (3)  $H_2O_2$ -generation by dual oxidase 2 (DUOX2), the dual oxidase maturation factor 2 (DUOXA2), and iodide oxidation and coupling by thyroid peroxidase (TPO). (4) Thyroid hormone secretion and iodotyrosine deiodination/iodide recycling by the iodotyrosine deiodinase (DEHAL1, encoded by the *IYD* gene). All these processes are regulated by TSH, while thyrocyte development and differentiation is coordinated by the thyrocyte enriched transcription factors NK2 homeobox 1 (NKX2-1), paired box gene 8 (PAX8), forkhead box E1 (FOXE1) and NK2 homeobox 5 (NKX2-5).

receptor and *TSH* may cause central or hypothalamic-pituitary hypothyroidism, while defects in the *TSHR* cause TSH resistance (Figure 84-1).

The thyroid gland secretes about 80% T4 and 20% T3 directly into the blood, where they are bound to three binding proteins: thyroxine binding globulin (TBG), transthyretin (TTR) and albumin (ALB). TBG has the highest affinity for T4 and T3, and carries the majority of T4 in serum. Saturation of the single binding site for T4/T3 on TBG is tightly regulated by TSH to adjust the concentration of unbound T4 (free T4) within narrow limits (11). Inherited defects in the thyroid hormone transport proteins do not cause altered metabolic state or thyroid disease. However, they produce alterations in thyroid hormone concentrations leading to inappropriate treatment if unrecognized (12).

Only recently, it has been shown, that thyroid hormone transporters are necessary for the intracellular availability of thyroid hormones to have access to the deiodinases and then nuclear thyroid hormone receptors (TRs) in the cell (13,14). The clinical importance of the specific thyroid hormone transporter monocarboxylate transporter 8 (MCT8) has been shown in patients with MCT8 mutations suffering from X-linked mental retardation, now referred as Allan–Herndon–Dudley syndrome (AHDS) (15).

Once intracellularly present, free T4, which is a pro-hormone of T3, is enzymatically deiodinated into the

active T3 by the selenoproteins deiodinase 1 (D1, mainly expressed in liver, kidney and thyroid) and deiodinase 2 (D2, mainly localized in brain, pituitary gland, placenta and brown adipose tissue). The inner-ring deiodinase 3 (D3) located predominantly in skin, brain and placenta converts T4 into inactive reverse T3, and T3 into inactive diiodothyronine (T2) (10,16,17).

So far no genetic defects have been identified in deiodinases 1–3 (D1–3), but recently missense mutations in a crucial cofactor for selenoprotein synthesis (SECISBP2) have been associated with mild alterations of thyroid hormone concentrations (18).

The major cellular actions of thyroid hormones are mediated by nuclear TRs via transcriptional regulation. Two *TR* genes, *alpha* and *beta*, encode five T3-binding receptor isoforms (alpha1, alpha2, beta1, beta2 and beta3). T3 binds with 10- to 15-fold higher affinity to TRs than T4 and is mainly responsible for mediating thyroid hormone action. T3 derives from circulating T3 monodeiodinated from T4 in peripheral tissues, from a limited amount (10–15%) of circulating T3 secreted by the thyroid gland, and from intracellular T3 derived directly from intracellular monodeiodination of T4 (19,20).

The transcriptional activity of TRs is regulated at multiple levels, especially by the developmental- and tissue-dependent expression of TR isoforms, and by nuclear co-regulatory proteins. In addition to TR-mediated gene

**TABLE 84-1 Genetic Disorders of Thyroid Function, Thyroid Hormone Transport, Metabolism and Action (Numbers Refer to OMIM Database Codes for Associated Disease)**

<b>Congenital Hypothyroidism</b>	
<i>Central: Hypothalamic–pituitary hypothyroidism</i>	
Pituitary dysgenesis	
Thyroid-stimulating hormone releasing hormone receptor deficiency (TRHR)	#275120
Thyroid-stimulating hormone beta subunit deficiency (TSHB)	#275100
<i>Thyroidal: Dysgenetic or dyshormonogenetic hypothyroidism</i>	
Thyroid dysgenesis	#218700
NK2 homeobox 1 (NKX2-1, TTF1) (Brain–lung–thyroid syndrome)	#610978
Paired box gene 8 (PAX8)	#218700
Forkhead box E1 (FOXE1, TTF2) (Bamforth–Lazarus syndrome)	#241850
NK2 homeobox 5 (NKX2-5)	#225250
<i>Resistance to TSH</i>	
Thyroid-stimulating hormone receptor (TSHR)	#275200
Gs alpha (GNAS) (Pseudohypoparathyroidism type 1a)	#103580
<i>Thyroid dyshormonogenesis</i>	
Sodium/iodide symporter (SCL5A5, NIS)	#274400
Thyroid peroxidase (TPO)	#274500
Dual oxidase 2 (DUOX2)	#607200
Dual oxidase maturation factor 2 (DUOX2A2)	#274900
Pendred syndrome (SCL26A4, Pendrin)	#274600
Thyroglobulin (TG)	#274700
Iodotyrosine deiodinase (IYD, DEHAL1)	#274800
<i>Peripheral: Disorders of thyroid hormone transport, metabolism or action</i>	
<i>Disorders of thyroid hormone transport proteins</i>	
Thyroxine binding globuline (TBG)	+314200
Transthyretin (TTR)	#145680
Albumin (ALB) (Familial dysalbuminemic hyperthyroxinemia)	+103600
<i>Disorders of thyroid hormone membrane transporters</i>	
Monocarboxylate transporter 8 (MCT8) (Allan–Herndon–Dudley syndrome)	#300523
<i>Disorders of iodothyronine deiodinase function</i>	
Selenocysteine insertion sequence binding protein 2 (SECISBP2)	#609698
<i>Thyroid hormone resistance</i>	
Thyroid hormone receptor beta (TRbeta) (generalized/pituitary)	#188570/#145650
<b>Genetic hyperthyroidism</b>	
Thyroid-stimulating hormone receptor (TSHR)	#609152
Gs alpha (GNAS) (McCune–Albright syndrome)	#174800
<b>Syndromes associated with hypothyroidism</b>	
Down syndrome	#190685
Turner syndrome	
Williams–Beuren syndrome	#194050
DiGeorge syndrome	#188400
<b>Genetic basis of autoimmune thyroid disease</b>	
<i>Autoimmune thyroid disease</i>	
Hashimoto disease/Graves' disease	%140300/%275000
<i>Autoimmune polyendocrine syndromes</i>	
APS type I/APS type II	#240300/%269200
IPEX syndrome	#304790
<b>Genetic basis of thyroid carcinoma</b>	
<i>Medullary thyroid carcinoma</i>	
Familial medullary thyroid carcinoma	#155240
Multiple endocrine neoplasia type 2A/2B	#171400/#162300

Papillary carcinoma	#188550
Follicular carcinoma	%188470

expression, there is increasing evidence for non-genomic effects of thyroid hormones in target cells that occur independently of nuclear TR binding (19,20). Inherited defects of TRs result in thyroid hormone resistance (21).

Optimal action of thyroid hormones in the human organism in iodine sufficient areas are dependent on the integrity of the entire hypothalamic–pituitary–thyroid tissue axis, normal thyroid hormone transport in blood, uptake into the cell and intracellular deiodination and binding to TRs. Table 84-1 gives a summary of genetic disorders of thyroid function and thyroid hormone transport, metabolism and action.

## 84.2 CONGENITAL HYPOTHYROIDISM

The essential role of thyroid hormones for brain development and skeletal maturation and growth has been clearly demonstrated and congenital hypothyroidism is one of the most frequent preventable causes of mental retardation. Neonatal screening programs have been established in the seventies of the last century in USA, Canada and Europe, and early diagnosis and substitutive treatment of congenital hypothyroidism has been shown to be highly sensitive, specific and cost-effective for prevention of congenital hypothyroidism-associated mental retardation (22–25).

Genetic defects leading to congenital hypothyroidism may occur at three levels: the hypothalamus and pituitary gland, the thyroid gland, or the peripheral tissue level. Possible abnormalities are listed in Table 84-1. Permanent congenital hypothyroidism affects about 1:3000–1:4000 newborns. Thyroidal congenital hypothyroidism outweighs by far the rare central or hypothalamic-pituitary congenital hypothyroidism cases. Girls are more commonly affected than boys (female to male ratio 2:1 to 4:1) and are more common in Hispanic infants (1:2000) than in white infants, and is thought to be less common in black infants (1:11,000) (6,26–29).

### 84.2.1 Hypothalamic-Pituitary Congenital Hypothyroidism

**84.2.1.1 Developmental Defects of the Pituitary.** Defects of pituitary development result in various forms of impaired secretion of pituitary hormones. Usually the clinical picture is characterized by multiple hormone deficiencies including TSH. However, the time course of manifestations of the different hormone deficiencies is highly variable and therefore congenital hypothyroidism may be the first and leading symptom of defective hypothalamic-pituitary development. Hypothalamic-pituitary disorders associated with hypothalamic-pituitary anomalies and disorders and with panhypopituitarism are reviewed elsewhere (see Chapter 83).

**84.2.1.2 Pituitary Hormone and Hormone Receptor Defects.**

**84.2.1.2.1 Thyrotropin-Releasing Hormone Receptor Deficiency (OMIM #275120).** To date no mutations have been described in the human *TRH* gene.

The human *TRH receptor* gene is localized on chromosome 8q23 (30). Targeted disruption of the *TRH receptor* gene in mice led to an unexpected mild phenotype of central hypothyroidism and hyperglycemia (31). Resistance to thyrotropin-releasing hormone has been reported in two families so far (32,33). In both families, the index cases bearing a compound heterozygous and a homozygous loss-of-function mutation, respectively, presented with growth retardation, clinical signs of hypothyroidism at 9 and 11 years of age without mental retardation, and showed absence of TSH and prolactin response after TRH stimulation test. The patients were not detected by TSH-based neonatal screening. In both families, the heterozygous family members were asymptomatic and had normal TSH and prolactin response to TRH.

**84.2.1.2.2 Familial-Isolated TSH Deficiency (OMIM #275100).** Isolated TSH deficiency due to *TSH-beta* subunit defects is a rare autosomal recessive cause of central congenital hypothyroidism. The first reported family was described in detail on clinical grounds by Miyai et al. (34) in 1971. The *TSH-beta* gene was cloned in 1988 (35), and allowed genetic investigations of the first described family, detecting the first mutation in the *TSH-beta* gene (36). Since then 11 different homozygous or compound heterozygous *TSH-beta* mutations have been identified so far. The 313delT mutation is the most prevalent mutation, was identified in different populations and is derived from a common ancestor (37). It causes severe congenital hypothyroidism. It involves a 1-bp deletion from codon 105 of the *TSH-beta* gene, converting a cysteine to a valine residue (C105V) and yielding an additional 8-amino acid non-homologous peptide extension on the mutant protein, which has lost biological activity (38). The hallmark of patients with *TSH-beta* mutations is congenital hypothyroidism not detected by TSH-based neonatal screening due to low or undetectable TSH levels in combination with low circulating thyroid hormones. TSH levels do not increase after TRH stimulation testing, while all other pituitary hormone axes respond normally to specific provocative tests excluding multiple pituitary hormone deficiency. The clinical phenotype of patients with homozygous or compound heterozygous *TSH-beta* mutations is variable, but severe forms of congenital hypothyroidism with mental retardation are commonly encountered if diagnosis and thyroid hormone substitution is delayed. Heterozygous family members are symptom free (34,38–41).

### 84.2.2 Thyroidal Congenital Hypothyroidism

In iodine sufficient areas the most common etiology of thyroidal congenital hypothyroidism is thyroid dysgenesis, representing 80–85% of all cases of permanent congenital hypothyroidism. Thyroid dysgenesis includes a spectrum of developmental abnormalities of the thyroid gland ranging from (1) “agenesis” or athyreosis (20–30%) due to a defect in survival of the thyroid follicular cell precursors, (2) ectopic thyroid gland (50–60%) mostly located in a sublingual position as a result of

**TABLE 84-2 Spectrum of Thyroid Morphology and Associated Malformations in Genes Causing Thyroid Dysgenesis or Resistance to TSH in the Human**

Mutated Gene	Thyroid Morphology				Associated Malformations
	Ectopy	Athyreosis	Hypoplasia	Normal Thyroid	
NKX2-5		One patient described			Cardiac defects (f)
FOXE1			One patient described	One patient described	Cleft palate, "Spiky" hair
PAX8					Kidney agenesis (f)
NKX2-1		Two patients described			Choreoathetosis, Lung disease (f)
TSHR		Apparent athyreosis			None

Gray cells represent expected phenotype.

f, facultative-associated malformation.

premature arrest of its migratory process or (3) hypoplasia of an orthotopic gland (5%). The term "apparent athyreosis" has been created to describe patients with no functional thyroid tissue on thyroid scans but demonstration of a thyroid gland remnant in ultrasound studies as well as measurable serum thyroxine and TG concentrations, suggesting presence of hypo-functional remnant tissue (26,42–44) (Table 84-2).

In 10–15% of patients, thyroidal congenital hypothyroidism is the consequence of defects of thyroid hormone synthesis (dyshormonogenesis) characterized by a normal or enlarged thyroid gland in normal position. Defects can occur in each step of thyroid hormone synthesis: iodide transport, TG synthesis or oxidation and coupling and are further detailed below (10,29,45).

While dyshormonogenetic cases are inherited in an autosomal recessive way, thyroid dysgenesis might be considered as a non-genetic condition to its mainly sporadic occurrence. In addition, the female predominance as well as the discordance of monozygotic twins argues against a classic Mendelian inheritance of thyroid dysgenesis. However, recent work has revealed some arguments for genetic basis of congenital hypothyroidism in some cases: First, although representing only a minority of cases of thyroid dysgenesis, familial cases were observed in a significantly higher proportion (>15-fold) than would be expected by chance alone. Second, an increased frequency of minor thyroid abnormalities in first-degree relatives of patients with thyroid dysgenesis has been described. Third, thyroid dysgenesis is associated with an increased incidence of associated extra-thyroidal malformations. A fourfold increase in congenital malformations was found in a population based study of 1420 infants with congenital hypothyroidism (8.4%) compared with the control infant population (1 to 2%) (26,27,42,46–49).

Nevertheless, non-Mendelian mechanisms need to be considered to explain thyroid dysgenesis in most cases. A multigenic origin of thyroid hypoplasia and hemiagenesis has been shown in transgenic mouse models, but discordance in monozygotic twins excludes multigenic origin of thyroid dysgenesis as the exclusive mechanism of its etiology in the human. Early somatic mutations or epigenetic modifications could play a role in thyroid dysgenesis development, in analogy with other human diseases. Recently,

Deladoëy et al. (50) proposed a two-hit model in analogy with focal hyperinsulinism: a germ line mutation (first hit) and a somatic mutation or epigenetic modification (second hit) of genes involved in critical steps of thyroid development. The hypothesis of a combination of germ line and somatic gene modifications is appealing for thyroid dysgenesis etiology, but needs to be confirmed (51).

**84.2.2.1 Thyroid Dysgenesis (OMIM #218700).** Based on the phenotype of transgenic mouse models mutational screening of cohorts of patients with thyroid dysgenesis led to the identification of mutations in genes involved in thyroid development: *PAX8* (1998), *FOXE1* (1998), *NKX2-1* (deletion 1998, mutation 2002) and *NKX2-5* (2006) (52–57). However, mutations in these four genes are only found in a small percentage of thyroid dysgenesis patients, even when screening large cohorts for each of the genes. So far, *NKX2-1* mutations with about 50 published cases are the most frequent cause of thyroid dysgenesis. *PAX8* mutations have been reported in about 30 patients and mutations in *FOXE1* and *NKX2-5* in less than 10 families so far. Further, Castanet et al. (58) showed by linkage and mutational analysis in 19 multiplex families genetic heterogeneity of thyroid dysgenesis: first, the LOD (logarithm of the odds) scores failed to prove linkage between *NKX2-1*, *PAX8*, *FOXE1*, and *TSHR* and thyroid dysgenesis, and second, no mutations in any of the four genes were found in 5 of the 19 families implicating novel yet unknown genes (59,60).

**84.2.2.1.1 NKX2-1 (Brain–Lung–Thyroid Syndrome) (OMIM #610978).** Based on the knowledge of NK2 homeobox 1 (*NKX2-1*, formerly *TTF1*) expression in the developing thyroid, lung and hypothalamus, the first patient with a *NKX2-1* deletion has been described in 1998 with the combination of infant respiratory distress syndrome at term, congenital hypothyroidism and hypotonia evolving to developmental delay (54). Heterozygous mutations of the *NKX2-1* gene have been first described in 2002, recapitulating the clinical triad of brain–lung–thyroid disease (55,57). Further, the neurological phenotype was described more precisely, revealing choreoathetosis or benign hereditary chorea (BHC) as a constant and specific sign for *NKX2-1* gene anomalies (61) (see Chapters 61, 117, and 118).

A recent review of 6 own and 40 published patients revealed that the clinical spectrum varies between the

complete triad of “brain–lung–thyroid syndrome” (50%), brain and thyroid disease (30%), to isolated BHC (13%), which represents the mildest expression of the syndrome. Thyroid dysgenesis ranges from hypoplasia (about 35%) to normal morphology (more than 50% of patients). Isolated hyperthyrotropinemia is more frequent than overt hypothyroidism at birth and later in childhood accounting for about 60% of patients. In addition, the severity of symptoms varies widely, even in families with the same disease-causing mutation. *NKX2-1* defects occur either as sporadic cases or as familial cases inherited in an autosomal dominant way (62).

Lung disease, if present at birth, manifests as surfactant deficiency syndrome and evolves in a subgroup of patients to interstitial lung disease with relevant mortality. Recently, it was shown that interstitial lung disease in patients with *NKX2-1* mutations was associated with altered surfactant protein metabolism (63).

BHC is the most constant sign of the triad that develops between 1 and 5 years of age and is nonprogressive in later life.

#### **84.2.2.1.2 Paired Box Gene 8 (OMIM #218700).**

Heterozygous *PAX8* mutations have been described since 1998 with a spectrum ranging from athyreosis to normal morphology; however, most patients displayed hypoplasia (56,64,65). Thyroid function also exhibits a large range from euthyroid patients to severe hypothyroidism, even within the same family. Failure of normal postnatal growth led to secondary hypoplasia in one family. Decreased iodide trapping and pathologic perchlorate test was described in the same family, suggesting thyroid dysmorphogenesis rather than thyroid dysgenesis as a basis of congenital hypothyroidism (64). Kidney agenesis or malformations are a facultative associated malformation in patients with *PAX8* mutations. So far 10 *PAX8* mutations are described.

**84.2.2.1.3 *FOXE1* (Bamforth–Lazarus Syndrome) (OMIM #241850).** Homozygous *FOXE1* (formerly *TTF2*) mutations have been shown to be the genetic basis for Bamforth–Lazarus syndrome, a rare syndrome characterized by cleft palate, athyreosis, spiky hair, choanal atresia and bifid epiglottis (52). In two families with a total of four patients athyreosis was found, while recently one patient was described with normally sized and located thyroid gland without radioactive iodide uptake on scintigraphy and very low TG levels and another patient with severe thyroid hypoplasia. All patients showed severe hypothyroidism. *FOXE1* mutations were not found in large cohorts of isolated cleft palate patients (66–69). Recently, the length of the alanine stretch within the normal *FOXE1* gene has been shown to influence the risk for thyroid dysgenesis, introducing a possible new role of *FOXE1* as a modifier gene of thyroid dysgenesis development (70).

#### **84.2.2.1.4 *NK2 Homeobox 5* (OMIM #225250).**

A higher prevalence of congenital heart disease has been

documented in children with congenital hypothyroidism than in the general population (48). Such an association suggested a possible pathogenic role of genes involved in both heart and thyroid development. The *NKX2-5* gene encodes a homeodomain-containing transcription factor with a major role in heart development. *NKX2-5* mutations have been shown to occur in 3% of patients with congenital heart disease without thyroid phenotype. Recently, four patients were described with heterozygous *NKX2-5* mutations with thyroid ectopy and athyreosis and severe hypothyroidism. Only one patient showed minor mitral valve insufficiency, the others having no cardiac phenotype (53,71,72). The exact prevalence and importance of this transcription factor in thyroid dysgenesis remain to be further characterized.

#### **84.2.2.2 Resistance to TSH.**

##### **84.2.2.2.1 Inactivating *TSHR* Mutations (OMIM #275200).**

The *TSHR* is localized in the basolateral membrane of thyroid follicular cells. The *TSHR* is a member of the G-protein-coupled seven transmembrane receptor family (73). The transmembrane domain interacts with G-proteins to activate the intracellular downstream cAMP pathway. The concentration of cAMP in the cytosol regulates proliferation and functional activity of thyroid follicular cells and the expression of thyroid specific genes as TPO, NIS and TG (74). The extracellular domain is responsible for high affinity binding of TSH. The *TSHR* gene is localized on chromosome 14q31 and consists of 10 exons. The extracellular aminoterminal domain is encoded by the first nine exons, while the transmembrane domain is encoded by the 10th exon (75).

TSH resistance was first described in a patient with congenital hypothyroidism, normal thyroid volume, but lacking uptake of radioiodide after exogenous TSH application (76). The first mutations in the *TSHR* gene was a compound heterozygous mutation found in three siblings with high TSH levels but normal T3 and T4 (hyperthyrotropinemia) (77). Since this initial report about 40 mutations have been described. The consecutive molecular mechanisms responsible for loss-of-function of the *TSHR* range from reduced cell-surface expression, probably due to misfolded protein structure and retention in the endoplasmic reticulum, reduced TSH binding, to impaired activation of the receptor or coupling to the intracellular G-proteins.

Congenital hypothyroidism due to mutations in the *TSHR* shows considerable disease heterogeneity, ranging from severe congenital hypothyroidism with severe thyroid gland hypoplasia to isolated hyperthyrotropinemia with normal thyroid volume. The severity of the disease is associated with genotype–phenotype correlations but is also dependent on biallelic versus monoallelic mutations in the same pedigree. Complete and moderate TSH resistance is mostly due to biallelic mutations inherited in an autosomal recessive manner and localized in exon 10 encoding the transmembrane domain (44,78–80), while mild resistance may occur by dominantly inherited monoallelic mutations (81).

The prevalence of *TSHR* gene mutations is higher than expected. In a Japanese cohort of patients with congenital hypothyroidism detected by TSH-based neonatal screening, *TSHR* gene mutations were found in 4.3% of patients with severe CH and 9.4% of patients with mild CH (82). Further, in adolescents with hyperthyrotropinemia but exclusion of autoimmune thyroiditis specific antibodies 11–29% of patients had monoallelic *TSHR* gene mutations in two Italian cohorts (83,84).

While severe cases always need T4 substitutive therapy for congenital hypothyroidism, controversy exists for proven partial TSH receptor defects. Several patients diagnosed at adult age with hyperthyrotropinemia remained euthyroid throughout life without any treatment, suggesting that elevated TSH could overcome the partial receptor defect (81,85,86). For such cases, detailed biochemical and molecular diagnostics is required to exclude mild forms of thyroid dysmorphogenesis that require treatment.

**84.2.2.2.2 Inactivating G-Protein Mutations (OMIM #103580).** A second form of TSH resistance with mild hypothyroidism can occur in pseudohypoparathyroidism type 1a due to inactivating mutations in the *GNAS* gene, which encodes the Gs alpha subunit of the G-protein. Patients usually present with short stature, round facies, shortening of the metacarpals and metatarsals, and obesity collectively termed as Albright hereditary osteodystrophy (10,45,87) (see Chapter 85).

**84.2.2.3 Thyroid Dysmorphogenesis.** Defects in any of the proteins indispensable for thyroid hormone synthesis lead to thyroid dysmorphogenesis and account for about 10–15% of congenital hypothyroidism with an incidence of 1:30,000–40,000 newborns (29,88,89). In these patients thyroid development and differentiation is normal; however, one of the critical steps of the synthetic machinery of the thyroid follicular cells is impaired. These include defects in (1) iodine uptake into thyroid follicular cells due to mutations in the *sodium/iodide symporter* (*NIS*, *SLC5A5*); (2) organification defects due to mutations in the *TPO*, *DUOX2* and *DUOX2* genes constituting the peroxidase enzyme system, or mutations in the *Pendrin* gene (*SLC26A4*); (3) defects in TG synthesis, storage or release; and (4) defective IYD (*DEHAL1*) activity leading to failure of thyroid follicular cell iodide recycling.

Patients with thyroid dysmorphogenesis are usually detected by neonatal screening suffering from congenital hypothyroidism, and present a goiter. As inheritance is autosomal-recessive, family history for congenital hypothyroidism and/or goiter is often positive (29,45). However, patients with different forms of thyroid dysmorphogenesis may develop mild hypothyroidism only during childhood or adolescence with or without goiter or present euthyroid goiter later in life.

For accurate clinical diagnosis of different forms of thyroid dysmorphogenesis, the kinetics of iodide uptake and release can be traced by administration of

radioiodide. After  $^{131}\text{I}$  administration an analysis of the thyroidal iodide concentration in relation to that in serum and the degree of iodine bound to protein can be obtained (45,90).

**84.2.2.3.1 Iodide Transport Defect (OMIM #274400).** Iodide uptake from the bloodstream into the thyroid follicular cell is the first step in thyroid hormone synthesis. Iodide is concentrated up to 40-fold by an active transport through the basolateral membrane. The iodide uptake is under close stimulatory regulation by TSH, especially in the context of low-iodine diet, and can be competitively inhibited by anions, such as thiocyanate or perchlorate, which are also used diagnostically (91,92).

The *sodium/iodide symporter* (*NIS*, *SLC5A5*) is a specialized plasma membrane glycoprotein that mediates active iodide transport at the basolateral membrane and is responsible for active iodide trapping from the bloodstream not only in the thyroid but also in other *NIS*-expressing tissues like mammary gland, salivary glands, gastric mucosa or placenta (91). Rat and human *NIS* genes were cloned in 1996 (93,94). Human *NIS* is located on chromosome 19. Expression of *NIS* is the limiting step for the onset of thyroid function in the human embryo at 12 weeks of gestation and the molecular explanation for accidental radioablation of the fetal thyroid by scintigraphy of pregnant women with radioactive iodide after the first trimester (4).

Iodide transport defect (ITD) is an uncommon form of dysmorphogenetic congenital hypothyroidism caused by *NIS* mutations transmitted according to an autosomal recessive pattern. Diagnostic criteria for ITD include a variable degree of congenital hypothyroidism and goiter, low or absent radioiodide uptake by the thyroid and other *NIS*-expressing organs (e.g. the salivary glands and gastric mucosa), and a low iodide saliva-to-plasma ratio (91,92,95). The first *NIS* mutation causing ITD was described in 1997 by Fujiwara et al. (96).

In a recent review of 31 patients with *NIS* mutations (97), a wide spectrum of severity and onset of hypothyroidism was observed. Genotype–phenotype correlations, however, revealed genotype specific onset of hypothyroidism at birth, during infancy or after the first year of life. Interestingly, patients with neonatal onset of hypothyroidism had the lowest residual radioiodide uptake on thyroid scintigraphy, compared to patients with infancy or childhood onset of hypothyroidism. This observation suggests that genotype-specific residual *NIS* activity in the thyroid gland may be a major determinant of the onset of hypothyroidism and the reason that patients suffering from milder forms of ITD will not be detected by neonatal screening (97).

**84.2.2.3.2 Iodine Organification Defects.** After uptake into the follicular cell at the basolateral membrane by *NIS* and efflux into the thyroid follicle at the apical membrane by *pendrin*, nearly 100% of the rare element iodide is rapidly bound in organic form (“organified”) (7,8,45).

This process takes place at the apical membrane of the thyroid follicle and is mediated by the enzymes TPO, DUOX2 in close contact with TG (98,99). For functional maturation of DUOX2, an endoplasmic reticulum resident DUOX2 is essential (100).

Iodine organification consists of oxidation of iodide to an active intermediate and iodination of tyrosyl residues of TG to form the iodotyrosines MIT and DIT. Then, these iodinated tyrosyl residues are linked to form T4 after coupling of two DITs and T3 after coupling of one MIT and one DIT. The enzyme TPO catalyzes iodination and coupling. For this it requires (1) hydrogen peroxide, which is provided by DUOX2 and possibly further NADPH oxidases and (2) iodine acceptors, which are the TG-bound tyrosyl residues.

Iodine organification defects (IODs) represent the most frequent cause of thyroid dysmorphogenesis and are either caused by defective TPO function or deficiency of hydrogen peroxide generation by DUOX2 or DUOX2A (45,101). In a recent study of 183 infants with congenital hypothyroidism, 14% of patients were diagnosed with an IOD (102).

IODs are classified as total (TIOD) or partial (PIOD) based on a perchlorate ( $\text{ClO}_4^-$ ) discharge test during thyroid scintigraphy with radioactive iodine. After administration,  $^{131}\text{I}$  is rapidly concentrated and organified in the thyroid follicle. Subsequent administration of perchlorate competitively inhibits further  $^{131}\text{I}$  uptake. In case of a normal organification process, radioactive iodide is iodinated and remains protein bound. As a consequence, less than 10% of the radioactive iodide is washed out. In TIOD, over 90% and in PIOD more than 10% of  $^{131}\text{I}$  is washed out after perchlorate administration, indicating that the  $^{131}\text{I}$  was efficiently concentrated within thyroid follicular cells but not organified sufficiently.

**84.2.2.3.3 TPO Deficiency (OMIM #274500).** TPO is a heme-containing enzyme at the apical membrane and is only active in the presence of hydrogen peroxide. TPO mediates organification of iodide and coupling of MIT and DIT. The human TPO gene is localized on chromosome 2p25, and consists of 16 coding exons. The nucleotide sequence was reported in 1987 (103). The first patient with a mutation in the TPO gene was a 12-year-old boy with compressive goiter due to noncompliance with substitutive therapy necessitating partial resection. He was diagnosed with overt hypothyroidism at the age of 4 months with congenital hypothyroidism. Biochemical studies of the resected thyroid tissue revealed absence of TPO activity. Subsequent DNA analysis identified a frame shift mutation (104). So far, about 60 mutations have been described and the majority of mutations are localized in exon 7, 8 and 9 of the gene, encoding the catalytic heme-binding domain of the protein. Patients with homozygous or compound heterozygous inactivating TPO mutations mostly show TIOD with goitrous congenital

hypothyroidism (105,106). However, recently few patients with PIOD have been described (107,108).

**84.2.2.3.4 Defects in DUOX2 (OMIM #607200) and DUOX2A (OMIM #274900).** Dual oxidase 2 (DUOX2, formerly referred as THOX2) and Dual oxidase maturation factor 2 (DUOX2A) form a heterodimeric NADPH oxidase complex at the apical membrane of the thyroid follicular cells. Together, they are the core of the  $\text{H}_2\text{O}_2$  thyroidal generating system, feeding TPO with  $\text{H}_2\text{O}_2$  for iodination and coupling. Human DUOX2 and DUOX2A are contiguous genes on chromosome 15q15.3. DUOX2 was cloned in 1999 and consists of 33 coding exons, while DUOX2A was identified only recently and consists of 6 exons (100,109,110). The existence of a NADPH oxidase dependent  $\text{H}_2\text{O}_2$  generating system was proposed as early as 1973 by Niepomniszcze et al. (111). They described an adult patient presenting with large goiter and IOD. After thyroidectomy, they observed restitution of iodination capacity of the thyroid tissue in vitro by addition of  $\text{H}_2\text{O}_2$ .

The first mutations in the DUOX2 gene were described in 2002 by Moreno et al. (112) by screening nine patients with molecularly unexplained IOD. They identified one homozygous mutation leading to severe congenital hypothyroidism and TIOD in one patient, while three patients were found harboring heterozygous mutations presenting with transient congenital hypothyroidism (112). Thus, in contrast to other dysmorphogenetic defects with autosomal recessive inheritance, haploinsufficiency of DUOX2 can result in transient congenital hypothyroidism. So far about 20 mutations have been described rendering the genotype–phenotype correlation more complex. Several authors have shown PIOD and transient congenital hypothyroidism in patients with compound heterozygous mutations. It has been postulated that dietary intake of iodine as well as residual function of the mutated DUOX2 protein might have modulated the phenotype of complete DUOX2 defects (113–115).

The first homozygous nonsense mutation in DUOX2A providing evidence for its critical role in thyroid hormonogenesis has been described in 2008 by Zamproni et al. (116). They screened the DUOX2A gene for mutations in 11 patients (10 Caucasian and 1 Chinese) with congenital hypothyroidism due to PIOD but negative for mutations in TPO and DUOX2. The index patient was of Chinese origin suffered from mild CH and PIOD. Pedigree analysis demonstrated recessive inheritance because heterozygous carriers had normal thyroid function including negative results in neonatal TSH screening. The Y246X mutation might be frequent in Chinese population, as 1 of 92 controls was identified as carrier (116).

**84.2.2.3.5 Pendred Syndrome (OMIM #274600).** The syndrome of familial profound congenital hearing loss associated with large multinodular goiter was first described by Pendred in two sisters in

1896 (117). The full triad of the syndrome is characterized by goiter of variable degree, PIOD and deaf mutism due to a specific malformation of the inner ear with enlarged vestibular aqueduct. Pendred syndrome is the only form of thyroid dyshormonogenesis with associated malformation. While the dysplastic cochlea with sensorineural deafness is a constant and leading clinical sign of the syndrome, goiter may be missing. Hypothyroidism is not a specific sign of the triad. Pendred syndrome is one of the most prevalent forms of syndromic deafness, with an estimated incidence of 10/100,000 individuals (118).

Pendred syndrome is caused by mutations in the *SLC26A4* gene encoding Pendrin, which was cloned in 1996. The *SLC26A4* gene is localized on chromosome 7 and has 21 exons. Pendrin expression is found in the thyroid, the inner ear and the kidney. Pendrin is localized at the apical membrane of thyroid follicular cells (119–123). The role of Pendrin in the thyroid is still in debate. In heterologous *in vitro* models, it has been shown that Pendrin facilitates iodide efflux from the thyroid follicular cells into the thyroid follicle at the apical membrane (124). However, there is no data available confirming the role of pendrin for apical iodide transport *in vivo* so far.

Thyroid dysfunction of Pendred syndrome consists of goiter in the context of PIOD. Goiter is of variable degree appearing during childhood. Thyroid function can be mildly hypothyroid or euthyroid even in patients with biallelic mutations. Most frequently, hypothyroidism is only seen in areas of low nutritional iodine intake (125,126). A hallmark of the syndrome is the large inter- and intrafamilial variability of the phenotype (127,128). To date, about 150 mutations have been reported in the *SLC26A4* gene. Several mutations are recurring in different ethnic groups: In Japanese and Korean patients, the H723R mutation accounts for about 50%, while in Europe mutations L236P, T416P and IVS8+1G→A are most frequently found (129,130).

As sensorineural deafness associated with enlarged vestibular aqueduct and not hypothyroidism is the leading clinical signs of the syndrome. Magnetic resonance imaging studies of the inner ear have been recommended in association with molecular genetic analysis for diagnosis of true Pendred syndrome (131) (see Chapter 142).

**84.2.2.3.6 Defective TG Synthesis and Transport.** TG is a homodimeric glycosylated iodoprotein with a molecular weight of approximately 650,000 Da. It is exclusively synthesized in thyroid follicular cells and released by exocytosis at the apical membrane into the thyroid follicle. It represents the most abundant protein of the thyroid tissue. Together with iodide and peroxide it is one essential substrate for thyroid hormone synthesis. TG contains tyrosine residues, which are the core matrix for organification and storage of MIT, DIT, T3 and T4. TSH stimulates colloid endocytosis at the apical membrane and TG proteolysis within the cytoplasm (132). The resulting T3 and T4 are released into

the bloodstream, while MIT and DIT are deiodinated by the IYD.

The human TG gene maps on chromosome 8q24.2 and contains 48 exons (133–135). TG is composed of three repetitive units and of an acetylcholinesterase-like domain at the carboxy-terminal domain, which is required for dimerization and intracellular transport (136).

Mutations in the TG gene are inherited in an autosomal recessive way. They occur in homozygous or compound heterozygous states. The first mutation in the TG gene was reported in 1991 (137). So far about 50 mutations have been identified in the last twenty years. Mutations of the TG gene can cause congenital hypothyroidism by three different ways: TG deficiency with little or no TG detected in thyroid tissues of patients (137,138), TG transport defect with accumulation of TG in the endoplasmic reticulum (139), and abnormally structured TG with defective iodotyrosine coupling and T4 deficiency (140). Interestingly, truncated TG protein might be secreted and could be sufficient for partial thyroid hormone synthesis as shown *in vitro* (135).

The majority of patients presents with severe congenital hypothyroidism with goiter at birth or appearing during infancy. Goiter can be detected already *in utero* (141). Typically, TG levels in blood are very low and show an absent rise of TG after stimulation with recombinant TSH, if applied. T4 is usually decreased, while T3 can be low or normal. The perchlorate test is negative in contrast to iodide organification defects. However, the phenotypic spectrum ranges from the severe cases to euthyroid goiter (141–144).

**84.2.2.3.7 IYD Defect (OMIM #274700).** The thyroid follicular cell recycles the iodide that is released from TG in form of MIT and DIT, while T3 and T4 are released into the blood. MIT and DIT are deiodinated by the IYD system. Failure to deiodinate thyroid MIT and DIT results in severe iodine deficiency due to severe iodine wastage, since these non-deiodinated iodotyrosines diffuse out of the thyroid and are excreted in urine. IYD defect was clinically described by several authors in 1950 (145,146). Patients showed hypothyroidism and goiters and suffered from cretinism. Radioiodide studies showed (1) an accelerated uptake of radioiodide (2) negative perchlorate test, (3) spontaneous release of labeled iodide and (4) high doses of labeled MIT and DIT instead of free labeled iodide in serum and in urine. About 25 pedigrees have been clinically described with a spectrum of cretinism, simple goiter or hypothyroidism and goiter (147). The IYD gene (*DEHAL1*) is localized on chromosome 6p24, and has 6 exons. The iodotyrosine deiodinase belongs to the NADH oxidase/flavin reductase superfamily (148). In 2008, Moreno et al. (149) identified the first homozygous mutations of the IYD/*DEHAL1* gene in four patients of different European countries. None of the patients was detected by neonatal screening but were diagnosed clinically with severe hypothyroidism appearing from infancy to

8 years of life (149). All had goiter, and two suffered from mental retardation. A further family with an *IYD/DEHAL1* mutation has been described (150). Interestingly, heterozygous family members were euthyroid and had no goiter.

### 84.2.3 Disorders of Thyroid Hormone Transport, Metabolism and Action

**84.2.3.1 Disorders of Thyroid Hormone Transport Proteins.** After hormone secretion from thyroid follicular cells into the blood, thyroid hormones are present in a free form and in a bound form. The bound form of thyroid hormones represent a large extra thyroidal pool of T3 and T4, while free T3 and T4 are transported into the cell, bind to the nuclear receptor and result in thyroid hormone dependent processes. Thyroid hormone serum transport proteins protect the body from fluctuations of thyroid hormone secretion. Approximately 0.03% of T4 and 0.3% of T3 are free or unbound in serum (12). The three serum thyroid hormone-binding and -transporting proteins are TBG, TTR and ALB. TBG binds 75% of T4 and T3 in serum, while TTR and ALB are responsible for 20% and 5% of thyroid hormone transport, respectively (11).

Disorders of serum thyroid binding proteins result in alteration of measured thyroid hormone concentrations but do not alter thyroid hormone dependent metabolic state of the body and do not cause thyroid disease. Thus, patients are clinically euthyroid but present with altered total T3 and T4 levels in the context of normal TSH. Often patients are treated inappropriately for biochemically diagnosed congenital hypothyroidism without clinical disease (45).

**84.2.3.1.1 Defects of TBG (OMIM +314200).** Inherited TBG defects may result in three different forms: complete TBG deficiency, partial TBG deficiency and TBG excess. The *TBG* gene is localized on chromosome Xq21 and is composed of five exons (151). Inheritance of *TBG* defects follows an X-linked pattern with complete phenotype in males or females with Turner syndrome.

Complete TBG deficiency has been first described in 1959 (152). Male patients are clinically euthyroid but are diagnosed on the basis of low total T3 and total T4 values in the context of normal TSH. TBG measurements reveal undetectable or very low TBG levels, while in carrier females, TBG levels are decreased by about 50%. Patients may be diagnosed by T4-based neonatal screening, but not if screening is based on TSH levels only. Based on neonatal screening data, the incidence varies from 1:1500 newborn in Japan to about 1:10,000 in Caucasians (153,154). Partial TBG deficiency is the most common form of TBG defects, with 1:4000 newborn. TBG levels are decreased but measurable, with milder disorders of T4 and T3 levels in affected males. A rare form of TBG defects is TBG

excess with a variable incidence in different countries (1:6000 to 1:40,000). Affected patients are characterized by clinically euthyroid state but increased total T4 in the context of normal free T4 and T3. TBG levels are increased by up to four times (12,155). So far 28 mutations have been associated with the three different forms of *TBG* defects (156).

**84.2.3.1.2 TTR Defects (OMIM #145680, #105210).** The first clinically euthyroid patient with increased TTR levels was described by Moses et al. (157). He was diagnosed based on elevated total T4 in the context of normal free T4, free T3, TSH, TBG and ALB. The *TTR* gene is localized on chromosome 18q11.2 and consists of 4 exons (11). Mutations in the *TTR* gene can cause changes in TTR concentration as well as decreased or increased affinity to T3 and T4. As TTR affinity to thyroid hormones is about 100 times less than for TBG, only mutations with increased affinity will be diagnosed as euthyroid hyperthyroxinemic patients (45,158). Some mutations of the *TTR* gene are associated with familial amyloidotic polyneuropathy or cardiopathy and with acquired and hereditary forms of system amyloidosis (159,160).

**84.2.3.1.3 Familial Dysalbuminemic Hyperthyroxinemia (OMIM +103600).** ALB represents about 50% of blood serum proteins in the human. ALB is carrier for steroids, fatty acids and thyroid hormones. The human *ALB* gene is localized on chromosome 4q11 and consists of 15 exons (11). Mutations in the *ALB* gene cause familial dysalbuminemic hyperthyroxinemia (FDH). It is the most common form of inherited euthyroid hyperthyroxinemia in Caucasians. FDH is transmitted in an autosomal dominant way. Patients are characterized by high total T4 due to increased affinity of ALB to T4 (161,162). In contrast to *TBG* and *TTR* defects, free T4 levels measured by standard clinical laboratory methods may also be falsely elevated. T3 levels are rarely increased (163). Genetic testing has been proposed to prove the disease as all FDH associated mutations have been identified in the 218 residues so far (163).

**84.2.3.2 Defects of Thyroid Hormone Membrane Transporters (OMIM #300523).** The effects of thyroid hormone on development and metabolism are exerted at the cellular level. Metabolism and action of thyroid hormones take place intracellularly, which require transport of the hormone across the plasma membrane. This process is mediated by thyroid hormone membrane transporter proteins. Many thyroid hormone transporters have been identified at the molecular level, although a few are classified as specific thyroid hormone transporters, including MCT8, MCT10 and organic anion-transporting polypeptide 1C1 (13,14). So far, mutations have only been described in the *MCT8* gene, which is located on the chromosome Xq13.2, consists of 6 exons and encodes for a protein with 12 predicted transmembrane domains. The hallmark of *MCT8* gene mutations is the combination of thyroid and neurological dysfunction

(15,164). Patients present during infancy with central hypotonia, poor head control, evolving to spastic quadriplegia, nystagmus and severe mental retardation with absence of speech. There are no other signs of hypothyroidism. The key laboratory finding is elevated T3 concentration in the context of low T4 and free T4. TSH levels are in the upper normal range. *MCT8* mutations have been associated with Allan–Herndon–Dudley syndrome and a Pelizaeus–Merbacher-like disease (165,166). So far, mutations have been found in over 50 families. Patients with unexplained mental retardation and abnormal thyroid function tests with low fT4, elevated T3 and normal to elevated TSH should be screened for *MCT8* mutations (14). Although females are heterozygous for the disease and asymptomatic, women are at risk to develop hypothyroxinemia during pregnancy. Therefore, heterozygous women should be monitored for hypothyroxinemia to avoid fetal and neonatal hypothyroidism and substituted if necessary to prevent cognitive delay (167).

**84.2.3.3 Defects in Iodothyronine Deiodinase Cofactors (OMIM #609698).** Intracellular metabolism of T4, which serves as prohormone and availability of the active T3 is regulated by the three selenoprotein iodothyronine D1–3. The three deiodinases serve as subunits of larger, functional enzyme complexes. The activating D1 and D2 can intracellularly increase the T3 level, while D3 is inactivating T4 to reverse T3 (10,16,17). The gene for D1 (*DIO1*) is located on chromosome 1, the genes for D2 and D3 (*DIO2* and *DIO3*) are found on chromosome 14 (16). Several human cases have been reported with suspected D1 deficiency (168,169). The patients were euthyroid with elevated levels of T4, free T4 and reverse T3, and low normal to normal levels of T3. However, no mutations have been found so far in *DIO1* or *DIO2*. Dumitrescu et al. (18) reported of three siblings with clinical evidence of abnormal thyroid hormone metabolism, presenting with high serum T4 and TSH concentrations, low T3 concentrations and markedly elevated rT3 concentrations. Their fibroblasts showed decreased D2 enzymatic activity but no *DIO2* mutation was found. Systematic linkage analysis of genes involved in D2 synthesis and degradation led to the identification of an inherited selenocysteine incorporation defect, caused by a homozygous missense mutation in the *selenocysteine insertion sequence binding protein 2* (*SECISBP2*) gene which serves as cofactor for deiodinase synthesis. An unrelated child with a similar phenotype was compound heterozygous with respect to mutations in *SECISBP2* (18). While these patients all presented clinically only with retarded growth, more recently, subjects with further defects in the *SECISBP2* gene were described with a much broader extra thyroidal phenotype due to reduced synthesis of most of the 25 known human selenoproteins, resulting in azoospermia, muscular dystrophy, photosensitivity, impaired T lymphocyte proliferation, abnormal mononuclear

cell cytokine secretion and enhanced insulin sensitivity (170).

**84.2.3.4 Thyroid Hormone Resistance (OMIM #188570, #145650).** In the nucleus, thyroid hormones are effective by binding to the TR. TRs belong to the nuclear receptor family and so far five isoforms have been identified (TR alpha 1 and 2, TR beta1, 2 and 3); however, the TR alpha 2 has no binding capacity for T3. TRs are mediating thyroid hormone effects by binding to thyroid-response elements in the promoter region of thyroid hormone responsive genes. Consequently, gene expression of thyroid responsive genes is up- or down-regulated. The expression of the different isoforms is tissue-specific (19,20,171).

The first family with resistance to thyroid hormone (RTH) has been described in 1967 by Refetoff et al. (172). This characterizes a syndrome with reduced responsiveness of target tissues of thyroid hormone. Mutations in the *TR beta* gene have been associated with RTH by Sakurai et al. (173). Since then, up to 1000 cases have been described in the literature with a wide range of clinical symptoms, 349 were reviewed in detail (21).

The clinical presentation is heterogeneous. Some patients have no or minor symptoms, others can present with symptoms of hypo- or hyperthyroidism. The characteristic diagnostic features of RTH are: (1) elevated serum levels of fT3 and fT4, (2) normal or slightly increased TSH levels that respond to TRH, (3) absence of signs and symptoms of hyperthyroidism and (4) goiter. Further clinical signs associated with RTH are attention-deficit hyperactivity disorder (ADHD) and learning disorders, mental retardation, recurrent ear, nose, throat infections, hearing loss and short stature during childhood, but not affecting adult height (174,175). Historically, two major forms have been described: generalized RTH (GRTH), and selective pituitary RTH (PRTH). GRTH patients are completely or partially compensating for decreased tissue responsiveness by increasing T4 synthesis. They are clinically euthyroid or hypothyroid. PRTH patients present with signs of hyperthyroidism. However, more recent data and genotype–phenotype correlation analyses found both, the two different forms in the same families with identical mutations. Thus, the two forms represent rather the wide clinical spectrum of RTH than two distinct forms (176,177).

So far, mutations were only identified in the *TR beta* gene, which is localized on chromosome 3, but none in the *TR alpha* gene. Inheritance is autosomal dominant. Most of the mutations cluster in the three domains of the T3-binding site of the TR beta molecule, while no mutations have been identified so far in the DNA-binding domain. As mutant TRs are forming homodimers with wild-type TRs, they are exerting a dominant negative effect on the normal TR loss of T3 binding, or reduced release of corepressor binding, as shown by in vitro experiments (178). In about 10% of families RTH occurs also in the absence of mutations in the *TR beta* gene (179).

### 84.3 GENETIC HYPERTHYROIDISM

#### 84.3.1 Activating TSHR Mutations (OMIM #609152)

While inactivating mutations of the *TSH receptor* gene (TSHR) cause congenital hypothyroidism, activating mutations can cause nonautoimmune hyperthyroidism. The three distinct forms of genetic hyperthyroidism are sporadic congenital hyperthyroidism caused by de novo germ line mutations, familial nonautoimmune hyperthyroidism due to autosomal dominant inheritance of germ line mutations, and autonomous adenomas caused by de novo somatic mutations (180). The first patient with sporadic congenital hyperthyroidism due to a de novo activating TSHR gene was reported in 1995 by Kopp et al. (181). Patients present at birth or during infancy with clinical signs and laboratory findings of hyperthyroidism: prematurity, low birth weight, goiter and craniosynostosis. In contrast to neonates with transient autoimmune hyperthyroidism due to placental transmission of activating TSHR autoantibodies from mothers with Graves' disease, patients with activating mutations have no antibodies and the disease persists beyond 3–6 months of life (181,182). Familial hyperthyroidism with autosomal dominant inheritance due to a gain-of-function mutation of the TSHR gene was first described by Duprez et al. (183) and so far 27 families have been reported. The onset of hyperthyroidism and goiter is highly variable, neonatal expression has been described. Both forms can be treated by antithyroid drugs, but often definitive cure is only possible by total thyroidectomy or radioablation. While in the two former forms all cells of the thyroid are hyperfunctioning, the monoclonal expansion of one mutated cell results in the development of an autonomous hyperfunctioning adenoma (45). The rest of the thyroid tissue is usually inactive. As gene expression profiling shows common characteristics, the different phenotypes of genetic hyperthyroidism are the result of the differences in intensity and onset of constitutive activity of the mutated receptor and its cellular distribution (184).

#### 84.3.2 Activating G-Protein Mutations (OMIM #174800)

McCune Albright syndrome is classically defined by the clinical triad of fibrous dysplasia of bone, café au lait skin spots and endocrinopathies, including precocious puberty, growth hormone and/or prolactin secreting pituitary adenomas, autonomous adrenal hyperplasia and hyperthyroidism (185–188). The disease results from somatic mosaicism for mutations of the *GNAS* gene. In patients with hyperthyroidism, the mosaic pattern involves the thyroid follicular cells leading to a constitutive activity of the Gs alpha protein. A review of patients with McCune Albright syndrome described the spectrum thyroid disorders ranging from nodular goiter with and

without overt hyperthyroidism, diffuse goiter with and without overt hyperthyroidism and hyperthyroidism without goiter. The thyroid hyperactivity is manifest in infancy or early childhood (188).

### 84.4 THYROID DISEASE ASSOCIATED WITH CHROMOSOMAL ABNORMALITIES AND CONTIGUOUS GENE DELETION SYNDROMES

Thyroid disorders have been reported to have a prevalence rate of 3–54% in individuals with Down syndrome (OMIM #190685) (189). The population-based incidence of medically treated thyroid disease in children with Down syndrome was 10.8% in a retrospective cohort study, with a 73-% increase after release of American Academy of Pediatrics guidelines in 2001 (190). The spectrum of thyroid disorders ranges from congenital hypothyroidism, autoimmune (Hashimoto) thyroiditis, to compensated hypothyroidism (hyperthyrotropinemia). The incidence of congenital hypothyroidism in newborns with Down syndrome is not precisely known, but was found to be as high as 3.5% compared with 0.5% in the general population (191). Cumulative percentage of patients developing hypothyroidism was 15% until 8 years, and 30% at 20 years. Hypothyroidism before 8 years was nonautoimmune, while most patients older than 8 years developed autoimmune thyroiditis (189). Routine screening for thyroid disease annually is recommended for children with Down syndrome (192) (see Chapter 43).

Individuals with Turner syndrome have an increased risk for autoimmune thyroiditis (193). In a longitudinal study 24% of 84 children with Turner syndrome developed hypothyroidism after a mean duration of 8 years (194). Annual screening for hypothyroidism is recommended from the age of 4 years on (193).

Patients with Williams–Beuren syndrome (OMIM #194050) and DiGeorge syndrome (OMIM #188400) have a high prevalence of thyroid hypoplasia (50–70%) and compensated hypothyroidism (25–30%) (195,196).

### 84.5 GENETIC BASIS OF AUTOIMMUNE THYROID DISEASE

#### 84.5.1 Familial Graves' Disease and Hashimoto Thyroiditis (OMIM %275000, %140300)

The two major autoimmune thyroid diseases (AITD) include Graves' disease and Hashimoto thyroiditis (see Chapter 76). Both disorders are characterized by infiltration of the thyroid tissue by T- and B-cells reactive to thyroid antigens, and the presence of autoantibodies against one or several specific thyroid proteins. Graves' disease is characterized by production of activating autoantibodies against TSH receptor (thyroid-stimulating immunoglobulins) by B lymphocytes. The thyroid-stimulating antibodies

bind to the TSH receptor, activate the TSH–cAMP cascade and finally causing hyperthyroidism. Hashimoto thyroiditis is characterized by lymphoid infiltration by autoreactive B- and T-cells leading to apoptosis, progressive autoimmune thyrocyte depletion, fibrosis and hypothyroidism. Autoantibodies against TPO and TG are a diagnostic feature of the disease (197,198). Both diseases arise due to complex interactions between environmental and genetic factors leading to the breakdown of self-tolerance.

Familial occurrence of AITD is well described, and both disorders may occur in the same family (197,199). Nearly one half of the first-degree relatives of patients with Graves' disease and Hashimoto thyroiditis have evidence of thyroid autoimmunity, with or without evidence of thyroid dysfunction. The ratio of the prevalence of the diseases in the siblings of affected individuals compared with the prevalence in the general population has been estimated to be 17 for AITD (11.6 for Graves' disease and 28.0 for Hashimoto disease) (197). Twin studies further support the inherited susceptibility to AITD, the concordance rate for Graves' disease and Hashimoto disease in monozygotic twins being as high as 35% and 55%, respectively (200,201).

The mechanisms of thyroid autoimmunity in Graves' disease and Hashimoto thyroiditis and the five- to 10-fold higher prevalence in females remain unclear. AITD susceptibility genes have been identified. They can be divided into immune modulating genes such as *HLA-DR*, *CD40*, *CTLA-4* and *PTPN22*, and thyroid specific genes like *TG* and *TSHR*. Amino acid substitutions in the *HLA-DR*, *TG* and the *TSHR* gene were found to predispose to AITD (197,202–204).

### 84.5.2 Autoimmune Polyglandular Syndrome (OMIM #240300, #269200, #304790)

The autoimmune polyglandular syndromes (APSs) are a group of diseases characterized by the presence of a combination of multiple autoimmune disorders. AITD occurs frequently in these patients (205–208).

APS-1 also called autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) is a rare monogenic disease caused by mutations in the *autoimmune regulator* (*AIRE*) gene. *AIRE* is assigned to chromosome 21q22.3 (209,210). To date, about 45 mutations have been described in *AIRE* inherited in an autosomal recessive manner. The decreased expression of the *AIRE* transcription factor results in the loss of central tolerance to self-autoantigens. Autoreactive T-cells target specific tissues like skin, parathyroid, adrenal glands and others. The diagnosis is made in the context of a combination of mucocutaneous candidiasis, hypoparathyroidism and Addison's disease. AITD is a common additional endocrinopathy in these patients occurring in about 10% (207,208).

APS-2 is the most common APS, also referred to as Schmidt or Carpenter syndrome. The combination of

Addison's disease with either AITD (Hashimoto thyroiditis or Graves' disease) or type 1 diabetes mellitus is diagnostic. Further non-endocrine autoimmune diseases associated with APS-2 are celiac disease, vitiligo, alopecia, pernicious anemia and myasthenia gravis. In contrast to APS-1, the inheritance of APS-2 is complex. Genetic association with HLA haplotypes (*HLA-DR3* and *HLA-DR4*) and polymorphisms of genes encoding immunologically relevant proteins (*MICA5*, 1, *PTPN22*, *CTLA4*, *VNTR*) have been described. The sum of these genetic factors confers a general susceptibility for the disease and the clinical spectrum of targeted organs. Circulating organ-specific autoantibodies are usually present even in the absence of overt clinical disease; 15% of relatives have autoantibodies detectable and manifest unsuspected illness, most commonly AITD (206–208).

IPEX syndrome is a rare X-linked condition of male infants resulting in multiple autoimmune disorders. The first symptom is severe chronic diarrhea due to autoimmune enteropathy. AITD occurs in the first year of life in 90% of patients (211). It is a result of absence or dysregulation of regulatory T-cells, caused by mutations in the *forkhead box P3* (*FOXP3*) gene (212). Children usually die within the first 2 years of life.

## 84.6 GENETIC BASIS OF THYROID CARCINOMA

### 84.6.1 Medullary Thyroid Carcinoma (OMIM #171400, #155240, #162300)

Medullary thyroid cancer (MTC) accounts for only 3–10% of all thyroid carcinomas, but up to 13% of deaths related to thyroid malignoma. MTC derives from calcitonin-producing parafollicular C-cells. A premalignant tumor stage is characterized by diffuse C-cell hyperplasia, followed by malignant transformation into MTC with or without metastases. Tumor size correlates with basal calcitonin levels, a reflection of tumor burden. In about 75% of cases, MTC is sporadic, unifocal with a peak incidence in the fifth and sixth decades. In 25% of patients, MTC is familial, inherited in an autosomal dominant trait, and is characterized by early onset in the first decade in the context of multiple endocrine neoplasia type 2 (MEN 2) (213–216). Three distinct but overlapping forms of MEN 2 can be distinguished: MEN 2A is characterized by the unique combination of MTC, pheochromocytoma and parathyroid hyperplasia/adenoma, MEN 2B comprises MTC, pheochromocytoma, mucosal and intestinal ganglioneuromatosis and Marfanoid habitus, and the familial medullary thyroid carcinoma (FMTC) is diagnosed in families with four or more cases of MTC in the absence of pheochromocytoma, parathyroid hyperplasia/adenoma or ganglioneuromatosis. In all three subtypes, MTC has a nearly 100% penetrance and is the first tumor of the syndrome to manifest (213–215).

The common genetic basis of the MEN 2 subtypes has been unraveled in 1993 by identifying gain-of-function germ line point mutations of the *rearranged during transfection* (*RET*) protooncogene in patients with MEN 2A, MEN 2B and FMTC (217,218). The *RET* gene was described in 1985 by Takahashi et al. (219). It is localized on chromosome 10q11.2 and contains 22 exons. The *RET* protooncogene belongs to the platelet-derived growth-factor (PDGF) family of protein tyrosine kinases. Its extracellular cysteine-rich domain is encoded by the first 11 exons, while the intracellular tyrosine kinase domain and the C-terminal tail are encoded by exons 12–21 (220). Most *RET* mutations are clustered in specific regions of the gene, coding for the extracellular cysteine-rich region (exon 10 and 11) and the intracellular tyrosine kinase domains 1 + 2 (exons 13–16) of the *RET* protein. *RET* mutations in MEN 2A and FMTC are inherited in an autosomal dominant manner. In contrast, *RET* mutations causing MEN 2B occur de novo (221,222). Inactivating mutations have been associated with Hirschsprung disease but it may also occur in patients with specific activating mutations in MEN 2A and FMTC (215,223,224).

Genetic testing for *RET* mutations has rapidly replaced biochemical screening by calcitonin measurements as first-line screening in asymptomatic kindred of MEN 2A and FMTC families in the last decade. It is currently the most specific and sensitive genetic screening in any of the hereditary cancer syndromes, and allows diagnosis and treatment in a preclinical disease stage for MEN 2A and FMTC, while MEN 2B patients need to be diagnosed on clinical grounds (213,215,225). Further, between 4 and 10% of apparently sporadic cases of MTC carry heritable disease-causing mutations in *RET* and *RET* gene mutation testing is widely recommended in all MTC patients (213,215,226).

Striking genotype–phenotype correlations characterize the MEN 2 subtypes and allow genotype-based prediction of MTC aggressiveness (227,228): MEN 2B is in 95% of cases caused by mutations in codon 918.

These patients develop the most aggressive form of MTC with metastatic disease as early as in the second year of life (221,222). In contrast, MEN 2A and FMTC show less aggressive MTC-phenotypes. Mutations at codon 634 represent the most frequent *RET* mutation (>60%) and result in the most aggressive MEN 2A phenotype (229,230). In 94 children with the c634 mutation undergoing total thyroidectomy until 20 years of age, 65% showed MTC and 16% metastatic MTC (230). Less frequent mutations in other codons typically show a slower development of MTC.

Genetic testing identifies at risk children in MEN 2A and FMTC families and allows “prophylactic” or early total thyroidectomy at a preclinical stage of disease. The strong genotype–phenotype correlations led to a refinement of the timing of total thyroidectomy based on codon-specific MTC aggressiveness initially into three risk categories (213). The current consensus guidelines have been published in 2009 by the American Thyroid Association (Table 84-3) and classify *RET* mutations into four risk levels (215). Risk levels also define the optimal age at prophylactic total thyroidectomy, the only curative approach for the thyroid disease. Patients with MEN 2B should be thyroidectomized during the first year of life, patients with MEN 2A or FMTC should undergo thyroidectomy according to codon-specific risk level. In general early total thyroidectomy at 5 years of age is a safe approach in any MEN 2A or FMTC patient unless baseline calcitonin is raised. In these cases immediate total thyroidectomy should be performed (213,215,230,231).

Although long-term results on prognosis are lacking, available data show that children with MEN 2A and FMTC undergoing prophylactic thyroidectomy until 5 years, respectively 8 years of age on the basis of genetic testing had no or lower incidence of recurrent or persistent MTC during follow-up than children operated at an older age (230,232). In contrast, as MEN 2B is due to de novo mutations, patients are often diagnosed with an advanced stage of MTC. Consequently they often suffer

**TABLE 84-3 American Thyroid Association (ATA) Medullary Thyroid Cancer Guideline 2009 (215)**

MTC Aggressiveness	ATA Risk Level	RET Genotype Mutated Codon	Phenotype	Earliest Age of MTC Onset	ATA Guideline for Prophylactic Total Thyroidectomy
Highest	D	918, 883, 804 + 805, 804 + 806, 804 + 904	MEN 2B	Infancy	<1 year
High	C	634	MEN 2A	1 year	<5 years
Moderate	B	609, 611, 618, 620, 630, 631, 633, 804 + 778	MEN 2A, FMTC	5 years	<5 years for higher risk mutations, alternatively*
Low	A	321, 531, 532, 515, 533, 600, 603, 606, 635, 649, 666, 768, 777, 790, 791, 804, 819, 833, 844, 866, 891	FMTC	>5 years	5 years, alternatively*

\*Prophylactic total thyroidectomy may be delayed in the setting of normal annual (1) serum calcitonin, (2) neck ultrasound, (3) less aggressive MTC family history, and (4) family preference.

from persistent or recurrent disease postoperatively with considerable mortality during childhood (221,222).

### 84.6.2 Thyroid Follicular Carcinoma (OMIM #188550, %188470)

Thyroid follicular cell tumors mostly occur sporadically, but familial forms do exist. Carcinoma of the thyroid in children and adolescents has little risk of mortality but high risk of recurrence. Younger patients present with a more advanced stage of disease (233,234). The clear association between radiation exposure and subsequent development of papillary thyroid carcinoma has been shown by Winship and Rosvall in 1961 (235).

Different genetic alterations are involved in thyroid tumorigenesis. Hyperfunctioning autonomous thyroid adenomas are considered to be clonal. The main mechanism responsible is the constitutive activation of the cAMP-dependent mitogenic cascade through somatic activating mutations of the *TSH receptor* or the *Gs* protein (184,236). In a series of 33 cases studied by Parma et al. (184), 82% were found to harbor a somatic *TSH receptor gene* mutation and 6% a *GNAS* gene mutation.

In a retrospective series from 1970–2000 of 56 patients between 4 and 20 years the histologic subtype of the thyroid tumor was pure papillary carcinoma in 66%, follicular variant of papillary in 29% and pure follicular carcinoma in 5% (233). No dedifferentiated tumors were observed. In adult patients papillary carcinoma, follicular carcinoma, poorly differentiated carcinoma and anaplastic carcinoma represent about 80, 15, 1 and 2% of all thyroid carcinomas, respectively (237). The distinct forms of thyroid carcinomas are characterized by different genetic alterations in signaling pathways. Papillary thyroid carcinomas are essentially characterized by mutations of the *BRAF* and *RAS* genes and *RET/PTC* rearrangement—all effectors of the MAPK signaling pathway—leading to constitutive activation of the pathway. The prevalence of *BRAF* is low in children while the prevalence of *RET/PTC* is significantly higher in pediatric PTC and children exposed to radiation after the Chernobyl nuclear accident than in adults (238–242). Follicular thyroid carcinoma is mainly associated with mutations of the *RAS* gene and the *PAX8-PPARGamma* rearrangement, while in poorly dedifferentiated and anaplastic thyroid carcinomas mutations in *RAS*, *BRAF*, *TP53* and *CTNNB1* are found (237,243).

Familial non-medullary thyroid cancer is rare. It can be classified in two groups: First, as non-syndromic forms occurring as (1) isolated familial papillary thyroid carcinoma (FPTC), (2) FPTC associated with renal cell carcinoma and (3) familial multinodular goiter. Second, as syndromic forms in the context of familial tumor syndromes such as (1) familial adenomatous polyposis syndrome and Gardner syndrome, (2) PTEN-hamartoma

tumor syndrome including Cowden syndrome, (3) Peutz-Jegher syndrome, (4) Carney complex and (5) Werner syndrome (244,245).

### Biographies

**Michel Polak, MD, PhD** Prof. Michel Polak is a pediatric endocrinologist and diabetologist, at Hôpital Necker Enfants Malades, 149 rue de Sèvres, Paris, France. He was born on 26 November 1962. He is a full professor at the faculty of Medicine, Paris Descartes University, and head, since 2002, of pediatric endocrinology gynecology and diabetology, at Hôpital Necker Enfants Malades, Paris, France. He is a member of the INSERM (National institute for health and medical research) U845 team.

His fields of special interests are fetal/perinatal endocrinology and in developmental biology and genetics, thyroid and endocrine pancreas development.

His training took place in Paris and during postdoctoral fellowships in the Department of genetics and microbiology, Centre Médical Universitaire, Genève, Switzerland and at Harvard Medical School, Department of Neurobiology (Prof. Potter) and Section of Immunology and Immunogenetics, Elliot P. Joslin Research Laboratory (Prof. Eisenbarth), Joslin Diabetes Center, Boston, MA, USA.

He has published more than 130 peer-reviewed papers in his field and was offered in 2003 the Jacques Raymond Ducharme award in pediatric endocrinology of the Sainte Justine hospital Montréal, Canada and in 2006 a French national award in medicine: “les victoires de la médecine” for the work on neonatal diabetes mellitus. Pr Polak was awarded the prestigious European Society for Pediatric Endocrinology research award in 2012.

**Gabor Szinnai, MD, PhD** Business address: Department of Pediatric Endocrinology and Diabetology University Children's Hospital Basel (UKBB), Spitalstrasse 33, CH-4056, Basel, Switzerland and Department of Biomedicine University Basel Mattenstrasse 28 CH-4058 Basel, Switzerland.

Clinical activity: General pediatric endocrinology, diabetology.

Research interest: Developmental genetics of the thyroid gland, genetics of human thyroid disease, physiology of water homeostasis regulating hormones. Dr Gabor Szinnai is consultant in Pediatric Endocrinology and Diabetology at the University Children's Hospital Basel with a research activity at the Department of Biomedicine of the University of Basel. His special interest is congenital thyroid disease. His initial work was focusing on genetics and development of medullary thyroid cancer in children with multiple endocrine neoplasia type 2. Then during a 3-year clinical and research fellowship at the Department of Pediatric Endocrinology, Hôpital Necker Enfants-Malades, University Descartes, Paris, the research interest was expanded to molecular mechanisms of congenital hypothyroidism. The current clinical and fundamental research activities are focusing on human genetics and developmental genetics of normal and pathologic thyroid development and function.

### 85.1 CALCIUM HOMEOSTASIS

The parathyroid gland plays a key role in calcium homeostasis by sensing a decrease in ambient calcium concentrations and responding appropriately by synthesizing and secreting more parathyroid hormone (PTH) (1). PTH acts on the kidney to enhance renal calcium reabsorption and promote conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D [1,25(OH)<sub>2</sub>D]. This active metabolite of vitamin D increases gastrointestinal absorption of calcium, induces osteoclast differentiation, and with PTH stimulates skeletal resorption, leading to increased extracellular calcium. The parathyroid gland responds to the normalization of the ambient calcium concentrations by reducing PTH release. The calcium-sensing receptor (CASR) is a plasma membrane G-protein coupled receptor (GPCR) that is expressed in the PTH-producing cells of the parathyroid gland and the cells lining the renal tubule (2,3). By virtue of its ability to sense small changes in circulating calcium concentrations ([Ca<sup>2+</sup>]<sub>o</sub>) and to couple this information to intracellular signaling pathways (thereby modifying PTH secretion and renal cation handling), the CASR plays an essential role in maintaining mineral ion homeostasis. Earlier studies showed that a cluster of missense polymorphisms—A986S, R990G, Q1011E—located in the cytoplasmic tail of the CASR is associated with interindividual population differences in [Ca<sup>2+</sup>]<sub>o</sub> (4,5). Different haplotypes are associated with primary hyperparathyroidism and the frequency of kidney stones (6). Recent genome-wide association studies in ~33,000 individuals of European and Indian Asian ancestry confirmed that the blood calcium concentration associated most significantly with SNPs in the CASR gene (7,8).

PTH also modulates the extracellular concentration of other ions, the most important of which is phosphate.

PTH-induced lysis of skeletal mineral [largely hydroxyapatite or Ca<sub>10</sub>(PO<sub>4</sub>)<sub>6</sub>(OH)<sub>2</sub>] increases extracellular phosphate as well as calcium levels. A compensatory decrease in extracellular fluid phosphate is brought about by the action of PTH-mediated inhibition of renal phosphate reabsorption, thereby inducing phosphaturia.

In target tissues, PTH itself binds to another GPCR, PTHR1, which also binds the related ligand, PTH-related peptide (PTHrP). The binding of PTH to its cognate receptor in bone and kidney is known to stimulate adenylate cyclase on the inner surface of the plasma membrane and induces increased phosphatidylinositol turnover (9). The adenylate cyclase product, cyclic AMP (cAMP), activates protein kinase A (PKA), while the products of phospholipase C activity, inositol-(1,4,5)-trisphosphate (IP<sub>3</sub>), and diacylglycerol (DG), mobilize intracellular Ca<sup>2+</sup> stores and activate protein kinase C (PKC). Thus, a cascade of intracellular signaling events is involved in target cell responses to PTH.

### 85.2 PRIMARY HYPERPARATHYROIDISM

#### 85.2.1 Clinical Features

Primary hyperparathyroidism is a common cause of hypercalcemia in adults. Multichannel autoanalyzer screening led to the recognition of its true incidence, presently estimated at about 1 per 1000 (10). The important laboratory features of primary hyperparathyroidism are elevated serum calcium, decreased fasting serum phosphate, increased serum PTH, and hypercalciuria. Although the disorder can present at any age, it occurs most frequently in the sixth decade. More women than men are affected, the ratio being about 3:1. When found

in children, primary hyperparathyroidism is likely to be a component of a familial endocrinopathy and a sex bias is not observed.

In primary hyperparathyroidism due to glandular hyperplasia, the hypercalcemia usually results from excessive PTH secretion due to increased parathyroid gland mass. In adenomatous disease, it is more often a change in control of PTH secretion by the parathyroid due to a resetting of the response to ambient calcium concentrations (11). Approximately 85% of cases involve a single benign adenoma, while hyperplasia (multiple hypercellular glands) is present in 15%. Parathyroid carcinoma is seen in less than 1% of cases, and ectopic secretion of PTH by nonparathyroid tumors is rare.

In primary hyperparathyroidism, other organ systems can be involved. These include the kidneys, skeleton, gastrointestinal tract, and central nervous system. Nephrolithiasis is the most important manifestation clinically, with kidney stones occurring in 20% of patients. Formally a classic sign, overt bone disease (osteitis fibrosa cystica, brown tumors, or pathological fractures) is uncommon. Gastrointestinal manifestations (nausea, vomiting, or constipation) are common but nonspecific; pancreatitis and peptic ulcer disease are now rare. In contrast, decreased bone mineral density (BMD), measured by dual-energy X-ray absorptiometry, is a more common mode of presentation. Because primary hyperparathyroidism may contribute to osteoporosis and increased fracture risk, a BMD measurement ("T-score") of  $-2.5$  or less at any site is now a criterion for parathyroid surgery (12). Even mild elevations of calcium can be accompanied with weakness and a feeling of lassitude. Major mood disturbances and psychotic behavior are associated with more severe hypercalcemia. Hypercalcemia and hypercalciuria lead to increased urinary frequency, and progressive nocturia is a common symptom. In more severe cases, dehydration and secondary electrolyte disturbances may also be present.

Hypercalcemia and elevated serum PTH levels are the biochemical hallmark of primary hyperparathyroidism. It is recommended that more than one measurement of these parameters be made, as values may be within the normal range early in the disease. Changes in serum proteins affect the ionized (biologically active) calcium fraction and total calcium values should be corrected for the albumin concentration or direct measurement of the ionized calcium made. Serum PTH should be assayed by a two-site immunoradiometric assay, which detects the intact molecule, preferably one of the new generations of assays detecting "bio-intact" (PTH 1-84) hormone. Elevated PTH levels occur in 90% of primary hyperparathyroid patients, but a high normal PTH level in the face of hypercalcemia indicates lack of suppression and is consistent with primary hyperparathyroidism. In interpreting a PTH result, it should be kept in mind that intact PTH levels increase in normal subjects after age 45, largely due to declining renal function. Serum phosphate

is usually at the lower end of the normal range because of the phosphaturic action of PTH. Hypophosphatemia occurs in about 25% of patients. To be diagnostically useful, serum phosphate measurements should be made in the fasting state to avoid postprandial fluctuations. Mild hyperchloremic acidosis is common because of the effects of PTH on renal chloride and bicarbonate handling. Urinary calcium is frankly elevated in one-third of patients. The effect of PTH on the renal 25-hydroxy-vitamin D-1 $\alpha$ -hydroxylase enzyme is reflected in serum 1,25(OH) $_2$ D levels at the upper end of the normal range or frankly elevated in one-third of cases.

## 85.2.2 Genetics

A single case report documented an R83X mutation in the *PTH* gene (MIM #168450, <http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM>), predicting a truncation after amino acid 52 of the mature PTH polypeptide (13). The patient exhibited hypercalcemia, skeletal changes of primary hyperparathyroidism but undetectable circulating intact PTH. While the patient's leukocyte DNA was heterozygous for the mutation, the wild-type *PTH* allele had been deleted in the tumor. Hence, the truncated mutant PTH that retained the biological active amino-terminal part was secreted from the gland and was active at PTH target tissues. Most, if not all, parathyroid adenomas and carcinomas are monoclonal cell expansions (14). Alterations in two genes, cyclin D1 (14) and multiple endocrine neoplasia type 1 (MEN1) (15), have been implicated in the development of some sporadic parathyroid adenomas. One study reported mutations in the target of the Wnt pathway,  $\beta$ -catenin, encoded by the *CTNNB1* gene (MIM #116806), in 3 of 20 parathyroid adenomas (16). However, this has not been replicated in other studies and  $\beta$ -catenin's involvement in the initiation or progression of parathyroid adenomatosis remains to be established (17). Cytogenetic loss of 13q14, containing the *RB* gene and other potential tumor suppressor genes, has also been implicated in parathyroid carcinoma (18,19). Abnormalities involving several other chromosomal regions have been observed in parathyroid adenomas (11), but the genes remain to be identified.

Ten percent of primary hyperparathyroidism cases are hereditary, occurring as an isolated form or associated with other abnormalities. Genetic linkage studies have confirmed the hereditary nature of these syndromes and in some cases identified specific mutations responsible for parathyroid hyperfunction (20–22). The entities discussed here are familial hypocalciuric hypercalcemia (FHH)/neonatal severe hyperparathyroidism (NSHPT), MEN1 and MEN2, the hyperparathyroidism-jaw tumor syndrome (HPT-JT), and familial isolated hyperparathyroidism (FIHP) (Table 85-1). The most common of these syndromes is MEN1, but the population frequencies are not well defined.

TABLE 85-1 Familial Hypercalcemic Syndromes <sup>a</sup>						
	FHH	NSHPT	MEN1	MEN2A	HPT-JT	FHPT

Associated conditions	Chondrocalcinosis Pancreatitis	—	Pancreatic islet and pituitary tumors; other neuroendocrine tumors (see Table 85-3)	MTC and pheochromocytoma (see Table 85-4)	Jaw fibromas; renal and uterine tumors	—

<sup>a</sup>FHH, familial hypocalciuric hypercalcemia; NSHPT, neonatal severe primary hyperparathyroidism; MEN, multiple endocrine neoplasia; HPT-JT, hyperparathyroidism-jaw tumor; FHPT, familial hyperparathyroidism; AD, autosomal dominant; AR, autosomal recessive.

**85.2.2.1 Genetic Counseling.** Individuals with idiopathic primary hyperparathyroidism should be carefully investigated for a hereditary syndrome if there is any suggestion of a positive family history. In sporadic cases, individuals should be advised that there is a low but non-negligible recurrence risk, since there is a small but significant genetic component to this multifactorial disease and it may be impossible on occasion to exclude a hereditary syndrome.

Surveys of recurrent FIHP have identified mutations of *CASR*, *MEN1*, and *HRPT2* genes (23–26). In these surveys, there are many families without evidence of any mutation and the possibility of unknown causative genes has not been excluded. In some families, FIHP is linked to a 1.7Mb region on chromosome 2p13.3-14 but the causative gene has yet to be identified (27). In any new family, first-degree relatives should be screened by measuring serum calcium and PTH, and affecteds should be counseled and considered for molecular testing.

**TABLE 85-2 Familial Hypocalciuric Hypercalcemia, Neonatal Severe Hyperparathyroidism, and Autoimmune Hypocalciuric Hypercalcemia Clinical Phenotypes**

Familial (benign) hypocalciuric hypercalcemia
Mild hypercalcemia and hypermagnesemia
PTH inappropriately normal
Parathyroidectomy ineffective in normalizing hypercalcemia
Renal calcium/creatinine clearance ratio <0.01
Renal concentrating ability normal
Neonatal severe hyperparathyroidism
Marked symptomatic hypercalcemia
Bony changes of hyperparathyroidism
Neurodevelopmental deficits if untreated
Parathyroidectomy recommended
Less severe forms now documented
Autoimmune hypocalciuric hypercalcemia
Phenocopy of FHH
Inactivating CASR autoantibodies

## 85.3 FAMILIAL HYPOCALCIURIC HYPERCALCEMIA

Almost 50 years ago a syndrome was described that was called familial benign hypercalcemia, which emphasizes the asymptomatic nature of the lifelong hypercalcemia. The syndrome was named as familial hypocalciuric hypercalcemia (FHH; MIM #145980) because of the abnormal renal calcium handling in affected family members (2).

The hypercalcemia of FHH is mild to moderate (Table 85-2). It is usually no more than 10% above the upper limit of normal, although occasional families may exhibit higher calcium concentrations. Fatigue, weakness, mental disturbance, and polydipsia/polyuria, common in primary hyperparathyroidism, are noted occasionally and are of lesser severity. In some FHH kindreds, affected individuals may have pancreatitis or gall stones, and an increased incidence of diabetes mellitus and cardiovascular disease has been suggested. Nephrolithiasis and peptic ulcer are not part of the syndrome.

In patients without increased parathyroid activity, skeletal radiographs and BMD are normal and susceptibility to fracture is not increased (28). Bone turnover is also normal although it may be mildly increased in a few patients. There is an increased incidence of chondrocalcinosis but this is not debilitating. Circulating levels of vitamin D metabolites and intestinal absorption of calcium are typically normal.

The degree of hypercalcemia in the majority of FHH patients is similar to that of mild primary hyperparathyroidism. In contrast to typical primary hyperparathyroidism, however, FHH is associated with increased serum magnesium. FHH patients demonstrate serum concentrations of PTH that are inappropriately normal, given the degree of hypercalcemia. While the majority of primary hyperparathyroid patients have elevated intact PTH, diagnostic difficulties can arise in differentiating FHH from the 10% of primary hyperparathyroid patients with PTH levels at the upper limit of normal.

Comparative review of diagnostic indices suggests that no single serum measurement may be adequate for differentiating primary hyperparathyroidism from FHH, although most cases will show a discordance between calcium and PTH concentrations (29). Helpful features in the differential diagnosis may be family history, serum magnesium, and assessment of renal calcium handling.

An important characteristic of FHH is the unusually high renal tubular reabsorption of calcium and magnesium in the face of hypercalcemia. In the majority of FHH patients, the renal calcium/creatinine clearance ratio is less than 0.01, while it is higher in patients with primary hyperparathyroidism and other hypercalcemic disorders (Figure 85-1). It should be noted that this lower limit for the calcium/creatinine clearance ratio is based on analyte concentrations measured in international (molar) units. It is also important to note that there are FHH families in which some affected members have increased calcium excretion or hypercalciuria (30).

In contrast to primary hyperparathyroidism, urinary concentrating ability in FHH is normal (2). The renal CASR may mediate the polyuria and diminished urinary concentrating ability typically seen with hypercalcemia in primary hyperparathyroidism. The CASR in the apical membrane of inner medullary collecting duct cells modulates vasopressin-controlled water permeability in that portion of the kidney.

Before identification of FHH as a distinct entity, affected patients thought to have primary hyperparathyroidism would undergo parathyroidectomy. In most instances, these patients remained hypercalcemic, and the present consensus is that surgery is to be avoided if the patient is asymptomatic. Moreover, the enhanced renal

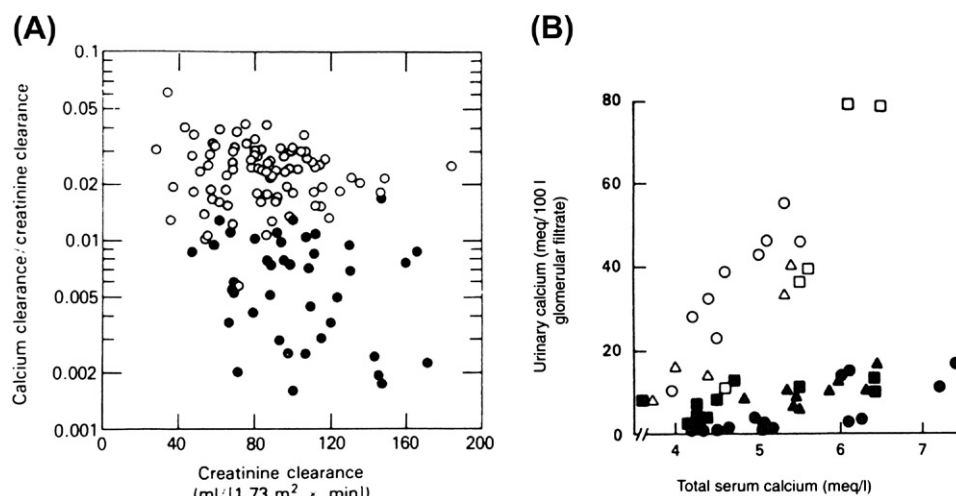

tubular reabsorption of calcium persists following induction of hypoparathyroidism by total parathyroidectomy, illustrating the fact that the abnormal renal handling of calcium in FHH is independent of PTH (see Figure 85-1).

## 85.4 NEONATAL SEVERE HYPERPARATHYROIDISM

Primary hyperparathyroidism occurs very rarely in childhood. Thirty years ago it was noted that three patients from two kindreds had severe (primary) hyperparathyroidism in the neonatal period. These and other identified cases of NSHPT (MIM #239200) involved multiglandular parathyroid hyperplasia rather than a single adenoma. Affected children under the age of 6 months develop severe, symptomatic hypercalcemia with the florid rickets and other bony changes of hyperparathyroidism. Delay in effective treatment can lead to a devastating neurodevelopmental disorder, if it is not fatal. Some forms of neonatal hyperparathyroidism, particularly *de novo* mutations of the *CASR* gene or secondary hyperparathyroidism, present with milder, less symptomatic disease that can be transient, so the decision to pursue a surgical solution requires frequent monitoring of serum calcium and clinical course.

### 85.4.1 Genetics

FHH is inherited in an autosomal dominant manner with almost 100% penetrance, but variable expressivity. The population prevalence of FHH is ill-defined, but it accounts for only a few percent of cases of asymptomatic hypercalcemia. This may reflect the infrequency of

**FIGURE 85-1** Altered renal handling in FHH patients. (A) Urinary calcium to creatinine clearance ratio in FHH patients (●) relative to values for primary hyperparathyroid patients (○). Eighty percent of FHH patients have a clearance ratio of less than 0.01, while primary hyperparathyroid patients rarely have such a low value. (From Marx, S. J.; Attie, M. F.; Levine, M. A., et al. *The Hypocalciuric or Benign Variant of Familial Hypercalcemia: Clinical and Biochemical Features of Fifteen Families*. Medicine (Baltimore). 1981, 60, 397–412, with permission.) (B) The abnormal renal handling of calcium is independent of PTH. This is shown by the difference in relationship between urinary calcium excretion in surgically aparathyroid FHH patients (●, ▲, ■) and hypoparathyroid patients (○, △, □). (From Attie, M. F.; Gill, J. Jr.; Stock, J. L., et al. *Urinary Calcium Excretion in Familial Hypocalciuric Hypercalcemia*. J. Clin. Invest. 1983, 72, 667–676.)

its recognition rather than the rarity of the disorder itself. The FHH locus was first mapped to 3q21-24 by linkage analysis. The trait in most FHH families map to the long arm of chromosome 3 (FHH1, MIM #145980), but in one was mapped to 19p13 (FHH2, MIM #145981). In a family from Oklahoma with atypical features (osteomalacia and increasing circulating PTH with age) and one other family, the condition mapped to 19q13.3 (FHH3, MIM #600740)(31). Thus, FHH is genetically heterogeneous.

In families with FHH and NSHPT and evidence of consanguinity, haplotype mapping of chromosome 3q markers closely linked to the FHH locus was consistent with NSHPT being the homozygous expression of the same disorder. The *CASR* locus was shown to reside on human chromosome 3q and the gene was further mapped to 3q13.3-21 by fluorescence in situ hybridization (FISH) (3). Mutation of the *CASR* gene is the most frequent cause of FHH and NSHPT.

### 85.5 *CASR* MUTATIONS IN FAMILIAL HYPOCALCAEMIC HYPERCALCAEMIA AND NEONATAL SEVERE HYPERPARATHYROIDISM

Almost 20 years ago, three different missense mutations (R185Q, E297K, R795W) in the 1078 amino acid receptor protein encoded by the *CASR* gene were identified in three unrelated FHH families. Since then, more than 100 additional inactivating mutations have been identified (Figure 85-2). The majority are missense with others being nonsense, insertion, and deletion/insertion. Two different missense mutants within the hydrophobic core of the NH<sub>2</sub>-terminal signal peptide cause marked impairment in cotranslational processing with little of the mutant *CASR* polypeptide entering the endoplasmic reticulum (32). In one case, an insertion of an Alu sequence in the *CASR* gene was shown and in another, a splice-site mutation was characterized (33). Several missense mutations are recurrent, and independent inactivating mutations to two different amino acid substitutions have been identified at some positions. The mutations are not evenly distributed but are clustered in two regions: the NH<sub>2</sub>-terminal 300 amino acids of the extracellular domain (ECD), and an approximately 340 amino acid stretch (residues 549–886) in the transmembrane and intracellular domains (see Figure 85-2). The *CASR* is constitutively dimerized in the endoplasmic reticulum and likely functions as a dimer at the plasma membrane (34). Heterodimerization of mutant and wild-type receptors may occur and some mutant receptors act in a dominant-negative way on the wild-type receptors.

Functional studies have been reported for some mutations and show that disruption of function may occur in a number of ways (30). Some mutated receptors fail to reach the cell surface. Others are targeted to the plasma membrane but show reductions in apparent affinity for

[Ca<sup>2+</sup>]<sub>o</sub>. And yet other forms of the receptor with mutations involving membrane-spanning segments show abnormal conformational changes following ligand binding. Mutations within the intracellular loops of the *CASR* may directly interfere with G-protein interaction. Finally, some receptors with de novo point mutations exert dominant-negative effects associated with milder (less severe) neonatal hyperparathyroidism. A more detailed review of *CASR* structure and function is given by Hendy and colleagues (3) and Hu and Spiegel (35), or can be found online in the *CASR* Locus-Specific Mutation Database (*CASRdb*; [www.casrdb.mcgill.ca](http://www.casrdb.mcgill.ca) (36)).

Parental transmission effects may occur in FHH as a result of maternal–fetal interdependence of calcium metabolism. The fetal calcium concentration is normally elevated above the maternal concentration, driven by PTHrP-stimulated placental calcium transport. The *CASR* in the placenta plays an important role in regulating this. Disruption of *CASR*, as seen in heterozygous or homozygous knockout mice, results in a further increase of fetal calcium concentrations.

In humans with FHH, neonatal hypercalcemia may be more severe than would be otherwise expected, much as if a form of secondary hyperparathyroidism existed in utero. This may be more prominent if the trait is inherited from the father or arises de novo, since the normal fetal calcium concentration set by the mother is sensed as low by the FHH fetal parathyroid gland (37,38). This may also occur in the heterozygous offspring of surgically hypoparathyroid NSHPT mothers. In most cases, the parathyroid gland overactivity is self-limited and the hypercalcemic hyperparathyroid state subsides after the first few months of life. Neonates with de novo *CASR* mutations that appear similar by in vitro functional analysis may, nonetheless, present with markedly different degrees of severity (39,40). Thus, factors such as vitamin D status (37) or general health of the mother may also play a role by modulating *CASR* expression from the normal allele. It is known that the active vitamin D metabolite, 1,25(OH)<sub>2</sub>D, and cytokines are important regulators of *CASR* gene expression (41–43).

Generally, late-onset primary hyperparathyroidism is not a part of the FHH syndrome and histologically the parathyroid glands removed from FHH patients are normal or mildly hyperplastic. This contrasts with the marked hypercellularity of the glands removed from NSHPT patients and *Casr* knockout mice. However, some FHH kindreds do include family members with hyperparathyroidism and it may be that certain *CASR* mutations, even in the heterozygous state, create a propensity to parathyroid cell proliferation (44). The apparent link between parathyroid calcium sensing and parathyroid cell proliferative pathways suggests that somatic alterations in the *CASR* gene could be tumorigenic. Although somatic *CASR* mutations are not a significant factor in parathyroid tumorigenesis, more than half of the parathyroid glands of patients with

primary and severe uremic secondary hyperparathyroidism show reduced CASR expression (11). Thus, mutations in growth-regulating genes may secondarily alter the calcium set-point by decreasing expression of the CASR. Evidence for this comes from a mouse model in which a cyclin D1 (*CCND1*, MIM #168461) transgene is under the control of the *PTH* gene regulatory region (45). Parathyroid gland CASR expression is reduced; the calcium set-point is shifted to the right; parathyroid enlargement occurs; and serum calcium and PTH levels are increased. In addition, the regulator of G-protein signaling 5 (*RGS5*) that inhibits signaling by the CASR is overexpressed in neoplastic parathyroid tissues (46). Therefore, reduced expression and/or activity may contribute to altered CASR signaling in parathyroid tumors.

Vitamin D metabolites have marked antiproliferative effects on the parathyroid gland. Patients with inherited disorders in which there is homozygous inactivation of the vitamin D receptor (*VDR*) or its ligand (and the corresponding mouse models of these disorders) manifest marked parathyroid hyperplasia (47). However, like the *CASR* gene, somatic mutation of the *VDR* gene, or the 25-hydroxyvitamin D-1 $\alpha$ -hydroxylase gene (*CYP27B1*) that locally produces the ligand, 1,25(OH) $_2$ D, does not contribute to parathyroid tumorigenesis, but parathyroid *VDR* expression is reduced in both primary and secondary hyperparathyroid patients. Vitamin D response elements that mediate upregulation of the *CASR* are present in both promoters of the gene (41). Thus, the reduced *CASR* expression may in part be secondary to decreased *VDR* expression. Additional evidence for the involvement of both the *VDR* and the *CASR* in controlling parathyroid function and/or growth comes from studies showing association of *VDR* and *CASR* gene polymorphisms (48) with primary and/or secondary uremic hyperparathyroidism.

*CASR* mutations have been found in two-thirds of FHH kindreds. In the remaining one-third, the molecular etiology is unknown. The disease may be due to mutations in portions of the *CASR* gene not yet examined. Secondly, a gene other than the *CASR* could be involved. Finally, an FHH phenocopy exists in those patients with anti-*CASR* autoantibodies associated with autoimmune disorders such as sprue or autoimmune thyroid disease (49,50). The anti-*CASR* antibodies interfere with elevated [Ca $^{2+}$ ]-mediated suppression of PTH release and perturb [Ca $^{2+}$ ]-sensing in the kidney, thereby closely mimicking FHH.

### 85.5.1 Genetic Counseling

FHH is relatively benign, but prospective parents may wish to determine the status of their spouse because NSHPT is not benign. Screening for a *CASR* mutation will confirm inheritance and allow unambiguous testing of family members with an equivocal phenotype, if a causative mutation is identified.

## 85.6 MUCOLIPIDOSIS AND NEONATAL HYPERPARATHYROIDISM

Mucopolipidosis II (ML II), or I-cell disease (MIM #252500) is a rare autosomal recessive lysosomal enzyme targeting disorder (see Chapter 103). ML II can present in the neonatal period with radiological and biochemical signs of hyperparathyroidism. It was suggested that the enzyme targeting defect of ML II interferes with transplacental calcium transport leading to a calcium-starved fetus with resultant secondary hyperparathyroidism to maintain fetal extracellular calcium concentrations (51,52).

## 85.7 MULTIPLE ENDOCRINE NEOPLASIA

The MEN syndromes are dominant conditions characterized by multiple tumors involving different endocrine glands. Familial recurrence of tumors in the parathyroid glands, the pancreatic islets, and the anterior pituitary is typical of MEN1 (MIM #131100), also known as Wermer's syndrome. In MEN2 (MIM #171400), also known as Sipple's syndrome, medullary thyroid carcinoma (MTC) occurs with pheochromocytoma and hyperparathyroidism. Although MEN1 and MEN2 syndromes are usually distinct and separate, occasionally patients develop tumors associated with both MEN1 and MEN2. There are rare examples of such cases in which mutations in both the *MEN1* and the *RET* genes have been identified (53,54). All forms of MEN are inherited in an autosomal dominant fashion, but sporadic occurrences are recorded. In some cases, the distinction may be difficult to make because of variability of expression or a negative family history.

## 85.8 MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

### 85.8.1 Clinical Features

Primary hyperparathyroidism occurs in 95% of MEN1 cases and is the first endocrinopathy to be detected in 90% of affected patients (Table 85-3). The hypercalcemia is generally mild. The mean age of onset is 20 years in the familial disorder vs. 55 years in sporadic primary hyperparathyroidism, and there is no sex bias (22). MEN1 patients should be followed carefully for the onset of symptoms and complications, at which time total parathyroidectomy should be considered. The life-long hypocalcemia is treated effectively with oral calcitriol [1,25(OH) $_2$ D $_3$ ] (15).

Pancreatic islet cell tumors develop frequently. The most common are gastrinomas, giving rise to the marked gastric acid production and recurrent peptic ulceration of the Zollinger–Ellison syndrome. This is the major cause of morbidity and mortality in MEN1 patients. Insulinomas and asymptomatic pancreatic polypeptidomas are also frequent, while glucagonomas and VIPomas are less

common. Anterior pituitary tumors occur in one-third of MEN1 patients and, of these, most are prolactinomas. However, somatotrophinomas, corticotrophinomas, and nonfunctioning pituitary tumors are also common. Other associated tumors include carcinoid, adrenal cortical carcinoma, thyroid follicular carcinoma, facial angiofibromas, collagenomas, and lipomas.

### 85.8.2 Genetics

More than two decades ago, the *MEN1* locus was mapped to chromosome 11q13 by linkage analysis in families and loss of heterozygosity (LOH) studies in MEN1-associated tumors. These studies indicated that MEN1 encodes a tumor suppressor, consistent with the Knudson two-hit model of tumorigenesis.

The *MEN1* gene was identified by positional cloning, and now more than 500 independent germline and somatic mutations have been found (55,56). Somatic mutations occur to a variable extent in parathyroid adenoma, gastrinoma, insulinoma, lung carcinoid, and anterior pituitary tumors. Many of the mutations lead to a truncated inactivated form of menin, the *MEN1* gene product (Figure 85-3). The lack of menin, caused by the loss of both alleles, leads to tumor development. Ten percent of the *MEN1* mutations occur de novo (55,56), and 25% of MEN1 patients do not have mutations in the coding region of the *MEN1* gene (57). Whether they have unidentified mutations in gene regulatory or untranslated regions remains to be seen. There is no apparent correlation between genotype and phenotype, and there is a wide diversity of mutations seen throughout the 1830bp coding region.

Human menin is a 610-amino acid protein without homology to known proteins. Two novel nuclear localization signals reside in the COOH-terminal portion and

menin is located predominantly in the nucleus. How loss of menin leads to tumorigenesis only in certain tissues, given that it is ubiquitously expressed, is unclear (58). Some MEN1 missense mutants of menin are selectively targeted to and rapidly degraded by the ubiquitin-proteasome pathway and the chaperone heat shock protein 70 (Hsp70) and the ubiquitin ligase, COOH terminus of Hsp70 interacting protein (CHIP) are important for this (59,60).

Menin is a scaffold protein and is a component of complexes important for chromatin remodeling, for example, the mixed lineage leukemia (MLL) complex. MLL has histone methyltransferase activity that controls *Hox* gene expression important for early development, and cyclin-dependent kinase inhibitors such as p18(Ink4c) and p27(Kip1) important for cell cycle control (61–63). It may be involved in telomere biology (64,65) and DNA replication and repair (66,67). Menin interacts with several transcription factors including Smads, JunD, and NF- $\kappa$ B and modulates their activities (58). It is a Smad3-interacting protein and inactivation of menin blocks transforming growth factor- $\beta$  (TGF- $\beta$ ) and activin signaling antagonizing their growth inhibitory properties in anterior pituitary cells (68,69). In cultured parathyroid cells, menin inactivation achieved by menin antisense oligonucleotides leads to loss of TGF- $\beta$  inhibition of cell proliferation and PTH secretion (70). Moreover, TGF- $\beta$  did not affect (decrease) the proliferation and PTH production of parathyroid cells from MEN1 patients (70,71). Loss of various TGF- $\beta$  signaling pathway components by genetic or epigenetic means is common in cancer and is likely to be important in MEN1 tumorigenesis (72).

Menin serves as a critical oncogenic cofactor of MLL fusion proteins in acute leukemias (73,74). Recently, the first crystal structure of a menin homolog from the sea anemone, *Nematostella vectensis*, has been reported (75). The protein core of menin comprises three tetratricopeptide motifs that are flanked by two  $\alpha$ -helical bundles and covered by a  $\beta$ -sheet motif. There is a large central cavity that constitutes the binding site for MLL.

Mice, heterozygous for genetic ablation of the *Men1* gene, develop and grow normally and only later in life express endocrine tumors similar to human MEN1 patients (76,77). Hence, humans and mice are haplo-sufficient for menin. In mice, homozygous deletion of *Men1* is an embryonic lethal. The affected fetuses die at midgestation with defects in multiple organs. They also show craniofacial hypoplasia, suggesting that menin might be implicated in bone development (78). Menin is required for the commitment of pluripotential stem cells into the osteoblast lineage (79,80). In this process, menin interacts physically and functionally with bone morphogenetic protein (BMP)-2 regulated Smads, such as Smad1 and Smad5, and the key osteoblast regulator, Runx2 (81). These interactions are lost as the committed osteoblasts differentiate further, at which time

**FIGURE 85-3** Distribution of germline and somatic mutations of the *MEN1* gene. Mutations shown above the exons are mainly nonsense or insertion/deletion causing a frameshift and introduction of a premature stop codon, and some cause errors in the splicing of the primary transcript. Mutations shown below the exons are missense or deletions, which do not change the reading frame. Hatched zones are untranslated regions of the mRNA, and NLS indicates nuclear localization sequence. (From Marx, S. J.; Agarwal, S. K.; Kester, M. B. et al. *Multiple Endocrine Neoplasia Type 1: Clinical and Genetic Features of the Hereditary Endocrine Neoplasias*. Rec. Prog. Horm. Res. 1999, 54, 397–439.)

menin interacts with Smad3, mediating the negative regulation of Runx2 by TGF- $\beta$  (81). Menin also suppresses osteoblast maturation, in part, by inhibiting the differentiation-promoting actions of JunD (82). Tissue-specific inactivation of menin in the mouse in neural crest cells (that contribute to several cell types including the mesenchymal stem cells that become osteoblasts) leads to perinatal death and cranial bone defects with decreased p27(Kip1) expression (83). Adult mice lacking the *Men1* gene only in osteoblasts demonstrate reduced bone mass (84).

## 85.9 MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

There are three distinct variants of this autosomal dominant disorder (Table 85-4). The most common is MEN2A (MIM #171400), in which MTC, which is seen in 95% of cases, occurs with pheochromocytoma (50%) and parathyroid tumors (20%). In MEN2B (MIM #162300), representing 5% of all MEN2 cases, hyperparathyroidism is rare, and MTC and pheochromocytoma occur together with developmental abnormalities such as Marfanoid habitus, mucosal neuromas,

**TABLE 85-4** Clinical Features of the MEN2 Variants

Type	Tumor	Associated Abnormalities
MEN2A (#171400)	Medullary thyroid carcinoma Pheochromocytoma Parathyroid	
MTC-only (#155240)	Medullary thyroid carcinoma	
MEN2B (#162300)	Medullary thyroid carcinoma Pheochromocytoma	Mucosal neuromas Marfanoid habitus Medullated corneal nerve fibers Megacolon

medullated corneal fibers, and autonomic ganglion dysfunction leading to multiple diverticula and megacolon. In familial MTC (MIM #155240), the medullary thyroid tumor is the sole disease phenotype. Hirschsprung disease and cutaneous lichen amyloidosis have also been described in MEN2.

### 85.9.1 Clinical Features

The clinical diagnosis of MTC is established by identifying hypercalcitoninemia ( $>90$  pg/ml), either in the basal state or following stimulation by intravenous pentagastrin (0.5 mg/kg) infusion. In the early stages, medullary thyroid tumors metastasize to cervical lymph nodes. Later, metastases may be found in mediastinal lymph nodes, lung, liver, trachea, adrenal gland, esophagus, and bone. Even when metastatic, however, MTC usually follows a relatively indolent course. In some, unfortunately, MTC pursues an aggressive course with widespread metastases and death. Total thyroidectomy with complete lymph node resection is the recommended treatment for MTC, followed by thyroxine replacement therapy (85).

Pheochromocytomas secreting norepinephrine and epinephrine occur in over half of all patients and constitute a major cause of morbidity and mortality. In MEN2, the incidence of bilateral involvement is 70%, which is much higher than the 10% bilaterality in non-MEN2 patients. Bilateral adrenalectomy may be the appropriate treatment for pheochromocytoma in MEN2A, even if radiological evidence suggests a unilateral tumor.

Primary hyperparathyroidism with elevated serum calcium and PTH occurs in 20% of MEN2A cases. This is due to parathyroid hyperplasia or multiple parathyroid adenomas. The incomplete suppression of PTH in response to a calcium infusion test and the observation of parathyroid hyperplasia at the time of thyroidectomy in MEN2A patients without clearcut hypercalcemia both suggest that parathyroid abnormalities are probably present in most cases.

### 85.9.2 Genetics

The *MEN2* gene maps to chromosome 10cen-10q11.2. This region contains the REarranged during Transfection (RET) proto-oncogene encoding a tyrosine kinase receptor (TKI) with cadherin-like, cysteine-rich ECDs and a tyrosine kinase intracellular domain (86). RET point mutations have been identified in all variants of MEN2 (87) ([www.arup.utah.edu/database/MEN2/MEN2\\_welcome.php](http://www.arup.utah.edu/database/MEN2/MEN2_welcome.php)). In MEN2A and FMTC, missense mutations predominantly occur in one of five cysteine codons (609, 611, 618, and 620 in exon 10 and 634 in exon 11). In 85% of MEN2A kindreds, this involves a RET codon 634 mutation (e.g., C634R), and in more than 50% of FMTC cases, a codon 618 mutation is found. Mutations in codons 768 (exon 13) and 804 (exon 14 within the intracellular tyrosine kinase domain) and in other parts of the protein occur in some FMTC kindreds (87). More than 95% of MEN2B patients have an M918T mutation in exon 16, at a site where the gene encodes the substrate recognition pocket of the tyrosine kinase catalytic core of the RET product (86). The receptor is a target for small-molecule inhibitors (88). Clinical trials of inhibitors of TKIs have shown positive responses in 30–50% of metastatic MTC patients (89).

The *RET* gene is a candidate for involvement in non-familial hyperparathyroidism. Although MEN2-type RET mutations—predominantly the M918T mutation of MEN2B—have been implicated in the pathogenesis of some sporadic MTCs and pheochromocytomas, no mutations have been found in sporadic parathyroid tumors. Mutations of the RET receptor ligand, glial cell-derived neurotrophic factor, do not appear to play a role in the genesis of MEN2 neoplasms, or in parathyroid adenomas.

### 85.9.3 Genetic Counseling

Testing for MEN2-type mutations is recommended in the diagnosis and treatment of patients with MEN2 and their families (85,90). Once a mutation has been identified, the 50% of related at-risk family members who do not have the mutation can be spared further biochemical screening. For carriers, total thyroidectomy may be recommended and constitutes a preventive cure (85). The earliest age of metastasis in MEN2A is 5 years; in MEN2B, it has occurred by 2 years of age, and therefore thyroidectomy should be pursued earlier (90). In at-risk patients, screening for excess catecholamine production should be performed annually.

## 85.10 MULTIPLE ENDOCRINE NEOPLASIA TYPE 4

Ten percent of MEN1 patients do not have detectable mutations of the *MEN1* gene and thus may have mutations in other genes. Attention was directed toward the *CDNK1B* gene that encodes the 196 amino acid CDKI, p27(Kip1), because of the finding that a naturally occurring rat model denoted as MENX that expressed a recessive MEN-like trait had a homozygous 8-bp frameshifting insertion at codon 177 of p27 with a missense peptide that terminated at codon 218 (91). The p27 protein was absent in rat tumor cells. In one family with MEN1 affected members were heterozygous for a germline *CDNK1B* W76X mutation (91). Other cases of mutations of p27 as well as other CDKIs, p15, p18, and p21, have been identified (92–95). It is to be emphasized, however, that such mutations are rare (~2%) in *MEN1* mutation-negative *MEN1* cases (96–100). MEN due to *CDKN1B* mutation has been designated as MEN4 (MIM #610755) to distinguish it from MEN1, MEN2A, or MEN2B (previously known as MEN3). Although parathyroid involvement is present in all MEN4 cases described to date, presentation of other MEN1-type tumors varies widely and the clinical phenotype is not clear-cut (101–103).

## 85.11 HYPERPARATHYROIDISM-JAW TUMOR SYNDROME

The HPT-JT syndrome is a multisystem disorder characterized by early onset of recurrent parathyroid tumors,

fibrous ossifying tumors of the mandible and maxilla, and tumors of kidney, uterus, and other organs (Table 85-5). Inherited in an autosomal dominant fashion, the syndrome shows a considerable range of expression (104). In a large group of families, this condition was linked to 1q21-31(105) and mutation analysis led to the identification of the responsible gene, *HRPT2*, which encodes a novel transcription factor, parafibromin/Cdc73 (106). Subsequently, studies of familial and sporadic parathyroid carcinoma suggest that the two-hit hypothesis of Knudson applies to the *HRPT2* gene and parathyroid carcinogenesis.

### 85.11.1 Clinical Spectrum

Patients with HPT-JT may be markedly hypercalcemic in childhood and adolescence, and there is a greater risk of hypercalcemic crisis than in the other variants of familial hyperparathyroidism. The condition may be associated with crippling skeletal disease and death. The incidence of parathyroid carcinoma is much higher than in sporadic hyperparathyroidism or MEN syndromes, potentially affecting more than 15% of hyperparathyroid patients carrying a mutant allele.

In contrast to the glandular hyperplasia found in other forms of inherited hyperparathyroidism, there is usually a solitary, enlarged cystic gland. After removal of a solitary tumor, the patient becomes normocalcemic, but double adenomas have been reported and recurrence is well documented.

TABLE 85-5 Screening for Manifestations of HPT-JT		
Tumor	Test(s)	Frequency
Parathyroid glands	Serum Ca, PTH <sup>a</sup> Neck ultrasound <sup>b</sup> <sup>99m</sup> Tc Sesta MIBI scan	Annually
Jaw fibromas	Panoramic X-ray	5 years
Renal lesions <sup>c</sup>	Abdominal MRI, renal ultrasound	5 years
Uterine <sup>d</sup>	Transvaginal ultrasound, endometrial biopsy	5 years

The age at which screening should be started has not been established, but affected children have been reported.

<sup>a</sup>Serum calcium and PTH may not always be sufficiently sensitive, and neck ultrasound may be added to the screening protocol. This is particularly important for carriers who have undergone partial resection and remain at risk for recurrence.

<sup>b</sup>Ultrasound-guided fine needle aspiration biopsy and analysis of the aspirate for PTH and/or thyroglobulin may be helpful in establishing the tissue of origin for any echogenic masses identified on ultrasound.

<sup>c</sup>Renal ultrasonography may be the first choice if access to abdominal MRI is limited.

<sup>d</sup>Screening for uterine disease should be guided by menstrual and reproductive history, as well as physical examination. If the history is negative and the preliminary ultrasound is normal, then a longer interval may be appropriate. Adapted from Bradley, K. J.; Hobbs, M. R.; Buley, I.D., et al. Uterine Tumours Are a Phenotypic Manifestation of the Hyperparathyroidism-Jaw Tumour Syndrome. *J. Intern. Med.* 2005, 257, 18–26.

Fibro-osseous jaw tumors are frequent, appearing as cystic lesions on radiographs. They are restricted to maxilla and mandible and their natural history is independent of the hyperparathyroidism. The tumors may be small and asymptomatic or they may be large, destructive, and recurrent. They consist of woven trabecular bone on a stromal background but the aberrant cell type has not been identified. However, the tumors lack osteoclasts and differ markedly from the brown tumors of longstanding untreated hyperparathyroidism, which also occur in the jaw but are often found elsewhere in the skeleton along with other signs of florid hyperparathyroidism.

Associated renal lesions include Wilms' tumor hamartomas, and polycystic kidneys. Uterine tumors include adenosarcoma, but benign adenofibromas and leiomyomas are more commonly reported. Benign or not, such tumors may have a significant impact on reproductive fitness (107).

Renal and uterine anomalies tend to occur in familial clusters, and are more common in patients who have jaw fibromas. A variety of other tumors have been described, but most are also seen in the general population, including carcinoma of the pancreas, prostate, thyroid, colon, and breast. Whether there is a predisposition to common cancers in some or all families is not known.

In a number of kindreds, only hyperparathyroidism is observed, adding to the genetic heterogeneity characteristic of FIHP (*HRPT1*; MIM #145000). FIHP is not the common presentation (24,25) for patients with an *HRPT2* mutation, but may account for a significant fraction of all affected families (108,109).

### 85.11.2 Genetics

HPT-JT and its variant forms are transmitted in an autosomal dominant manner with incomplete, age-dependent penetrance. Although the variability of the phenotype is reduced within families that share a common mutation and similar genetic background, genotype–phenotype correlations have not yet emerged. The *HRPT2* locus located at 1q25-q32 encodes a single-copy gene (*CDC73*) of 17 exons that produces a mature transcript of 2.7 kb and predicts a protein originally named parafibromin of 531 amino acids (110). The COOH-terminal half of parafibromin has homology with the yeast cell division cycle protein 73 (*Cdc73*) (106). Hence dual designations of the gene, *HRPT2/CDC73* (MIM #607393) and the protein, parafibromin/Cdc73, may be found in the current literature. Parafibromin is a ubiquitously expressed and predominantly nuclear protein (111): a nuclear localization signal resides at amino acids 125–139 (112,113) and a nucleolar localization signal is at amino acids 76–92 (114,115). Parafibromin is a component of the Polymerase Associated Factor 1 complex that interacts with RNA polymerase II and is involved in transcript elongation and mRNA 3' end processing (116,117). Like menin, the product of the *MEN1* gene,

parafibromin can function as a tumor suppressor or an oncogene in a cell context-dependent manner. For both, their binding proteins determine their particular functional roles in transcription that can direct opposing responses either promitogenic or antiproliferative. For example, the protein tyrosine phosphatase, SHP2, encoded by the *PTPN11* gene, dephosphorylates parafibromin (118) converting it from a transrepressor of c-myc (119) and cyclin D1 (111) into an activator of promitogenic Wnt signaling by interacting directly with  $\beta$ -catenin (120).

Most of the mutations identified to date (>110; two-thirds, germline; one-third somatic) involve truncation or premature stops (121). Nearly half of the mutations are found in exon 1, while most of the remainder are found in exons 2 and 7. Exons 3–6, 8, and 14 are also mutation sites, but mutations in the 3' half of the cDNA sequence occur much less frequently. Mutations are only detected in about half of HPT-JT families, even when there is evidence linking the family disorder to chromosome 1q31.2. Moreover, de novo mutations have been identified and parental mosaicism is reported (109).

### 85.11.3 HRPT2 in Parathyroid Carcinoma

Somatic *HRPT2* mutations are not found in sporadic typical benign parathyroid adenomas (122). In parathyroid carcinomas, LOH at chromosome 1q, particularly in tumors from HPT-JT kindreds, has been well characterized, supporting a tumor suppressor function for parafibromin (106). Studies of sporadic parathyroid carcinomas show somatic mutations of the *HRPT2* gene in tissue, while carcinomas in HPT-JT kindreds show tissue LOH in affected carriers (108,123,124). Of particular note is the finding that patients with apparently sporadic parathyroid carcinomas harbor germline mutations (108,124). Parathyroid carcinoma is potentially resectable when contained within the gland, but difficult to control when it has metastasized, so it would be recommended that all patients with newly diagnosed parathyroid carcinoma should have a careful review of family history, and should be offered *HRPT2* mutation screening, if there are family members at risk (125). Parafibromin immunostaining (see below) may serve as a clinical screen for tumors resulting from a germline *HRPT2* mutation that will help direct molecular testing for patients and families most at risk. Guidelines have been proposed and screening of asymptomatic carriers is now recommended (see Table 85-5).

Distinction between parathyroid carcinoma and adenoma is difficult using histopathological criteria (20,126). Features of parathyroid cancers, parenchymal mitoses, trabeculated parenchyma including thick fibrous bands, and capsular and vascular invasion may also be found in atypical adenomas. Capsular and lymphovascular invasion is the most specific histopathological feature of parathyroid carcinoma. Therefore, identification of

useful immunohistochemical tumor markers has become of primary importance. To date, parafibromin, either alone or in combination with other markers, is one of the most promising. An initial report (127) found that loss of nuclear parafibromin expression identified parathyroid malignancies with near absolute sensitivity and specificity with more recent reports observing somewhat lower specificity and sensitivity while still finding it to be a useful marker (128–130). Combination with staining for other markers has been proposed to offer advantages over staining with parafibromin alone, for example, loss of *RB1* and overexpression of galectin-3 (131). The combined loss of parafibromin staining and downregulation of *CASR* expression indicates increased malignant potential in parathyroid carcinoma patients (132).

## 85.12 OTHER HEREDITARY HYPERPARATHYROIDISM

FIHP (or HRPT1; MIM #145000) has been defined as hereditary primary hyperparathyroidism without the association of other disease or tumors. A small proportion of these cases have now been shown to be variants of the other monogenic diseases—FHH, MEN1, or HPT-JT—but in other cases additional genes as yet unknown are likely to be involved. As pointed out above in some kindreds, FIHP is linked to a region on chromosome 2p but the causative gene has yet to be identified (27).

## 85.13 DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF HYPERCALCEMIA

With the frequent detection of hypercalcemia in biochemical screening programs, the differential diagnosis of primary hyperparathyroidism from other conditions causing hypercalcemia has become increasingly important. Causes of nonparathyroid hypercalcemia include humoral hypercalcemia of malignancy, vitamin D or A intoxication, milk-alkali syndrome, granulomatous disorders (especially sarcoidosis), immobilization of patients with a preexisting high bone turnover state, thyrotoxicosis, Paget's disease, and treatment with thiazide diuretics or lithium.

Malignancy is a common cause of hypercalcemia. Although the hypercalcemia can occur through several different mechanisms, increased osteoclastic bone resorption is often involved. PTHrP is the major causative agent in the humoral hypercalcemia of malignancy—especially in squamous cell carcinomas (e.g., lung, head and neck, esophagus), cancer of the breast, kidney, and ovary, and T-cell lymphomas—although many other circulating factors may contribute.

Study of the relatives of patients with hypercalcemia can contribute to establishing the diagnosis in 10–15% of all cases of primary hyperparathyroidism that prove to be hereditary. The finding of another relative with hypercalcemia furnishes evidence of primary

hyperparathyroidism, if FHH is not suggested by a relatively low urinary calcium/creatinine clearance ratio or definitively diagnosed by the identification of a mutation of the *CASR* gene. The finding of a hypercalcemic relative also requires investigation of the patient for manifestations of the MEN or HPT-JT syndromes. The diagnosis of FIHP is made by exclusion of FHH, MEN, and HPT-JT. With the development of improved hormone immunoassays, it is now less likely that an MEN1 family, for example, would be classified as FIHP. Genetic testing may be helpful in that identification of a mutation in the *MEN1* gene should clinch the diagnosis of an MEN1 variant, alerting the surgeon to the likelihood of parathyroid hyperplasia, and prompting the physician to search for other endocrine abnormalities.

### 85.13.1 Management

Parathyroidectomy by an experienced surgeon is the treatment of choice (133). In cases of multiglandular disease, total parathyroidectomy is the definitive treatment and the patient is maintained on lifelong calcium and vitamin D supplementation. Some centers perform either a subtotal parathyroidectomy (removal of 3½ glands), or a total parathyroidectomy with autotransplantation of parathyroid tissue into the nondominant forearm (133). However, persistent or recurrent hypercalcemia may ensue if the transplanted tissue resumes its autonomous growth, necessitating further surgery.

Criteria for surgery in hyperparathyroidism have been established by a consensus conference at the National Institutes of Health (12). Asymptomatic patients who are treated conservatively with twice yearly serum calcium and urinary calcium excretion determinations and yearly bone densitometry generally do well and the progression of the disease is slow. Medical therapy (estrogens, progestins) is, at present, usually unsatisfactory if there is symptomatic disease, and is reserved for patients unable to undergo surgery. Bisphosphonate may be a useful alternative to parathyroidectomy in asymptomatic primary hyperparathyroidism among those with low BMD (134). In another study, primary hyperparathyroid patients with serum calcium levels above 2.8 mmol/l underwent intravenous infusions of pamidronate 1 month before parathyroidectomy. There is a short and limited calcium-lowering effect of bisphosphonate treatment, so it cannot be considered as an alternative to surgery (135). In a third study, the successful use of short-term intravenous pamidronate to treat the extreme hypercalcemia of NSHPT and halt hyperparathyroid-driven skeletal demineralization in preparation for parathyroidectomy (so-called rescue therapy) has been described (136).

Calcimimetics, orally active compounds that increase the sensitivity of the parathyroid *CASR* to extracellular calcium thereby reducing PTH secretion, offer a non-surgical approach for management of hyperparathyroid

states (137). The calcimimetic, cinacalcet, is approved clinically in North America for secondary hyperparathyroid patients with chronic kidney disease on dialysis and patients with parathyroid carcinoma (and those with primary hyperparathyroidism in Europe). Cinacalcet was found to reduce hypercalcemia in two-thirds of patients with inoperable parathyroid carcinoma in an open-label, single-arm study and may be an option for treatment of such patients (138). Also several off-label uses of cinacalcet have been reported (139). In an infant with neonatal hyperparathyroidism secondary to a de novo heterozygous *CASR* mutation, treatment with cinacalcet decreased PTH secretion and serum calcium levels and mitigated the need for parathyroidectomy (38).

### 85.14 JANSEN METAPHYSEAL CHONDRODYSPLASIA (PSEUDOHYPERPARATHYROIDISM)

Direct evidence that the parathyroid hormone receptor, PTHR1, mediates the calcium homeostatic actions of PTH and the skeletal actions of PTHrP comes from the study of Jansen metaphyseal chondrodysplasia (JMC; MIM #156400). This condition is inherited in an autosomal dominant fashion, although most reported cases are new mutations. Important features include short-limbed dwarfism secondary to severe growth-plate abnormalities, asymptomatic hypercalcemia, and hypophosphatemia (140). A milder form of metaphyseal chondrodysplasia with nephrolithiasis and suppressed serum PTH, but normal height and serum calcium, may also be seen (141). There is increased bone resorption similar to that in primary hyperparathyroidism and urinary cAMP levels are elevated, but circulating PTH and PTHrP levels are low or undetectable. Although the PTHR1 is found widely in fetal and adult tissues, it is most abundant in three sites—kidney, bone, and metaphyseal growth plates. Molecular analysis shows that the altered mineral ion homeostasis and growth-plate abnormalities of JMC are the result of heterozygous gain-of-function mutations (Figure 85-4) in the *PTHR1* gene—that maps to 3p21.1-22—giving rise to constitutively active receptors (141). Diagnosis is based on the combination of radiological assessment and biochemical profile.

### 85.15 PRIMARY HYPOPARATHYROIDISM

Primary hypoparathyroidism is caused by a group of heterogeneous conditions in which hypocalcemia and hyperphosphatemia occur as a result of deficient PTH secretion (142). Hypoparathyroidism most commonly occurs as a result of surgical excision of, or damage to, the parathyroid glands. Genetic forms of hypoparathyroidism due to decreased secretion of PTH are listed in Table 85-6.

**FIGURE 85-4** Schematic representation of the human PTHr1. The locations of the H223R, T410P, and I458R activating mutations identified in patients with Jansen metaphyseal chondrodysplasia, the R104X, P132L, V365del-1fsX505, and Δ373–383 inactivating mutations found in patients with Blomstrand chondrodysplasia, the R485X Eiken syndrome mutation, the G121E, A122T, R150C, and R255H enchondromatosis mutations, and the E155X primary failure of tooth eruption (PFE) mutation are indicated. Splice-site mutations that would result in predicted mutant C351fsX485 and E182fsX203 proteins have been identified in additional PFE cases.

### 85.15.1 Clinical Features

The signs and symptoms of hypoparathyroidism include evidence of latent or overt enhanced neuromuscular excitability due to hypocalcemia (Table 85-7). The effect may be aggravated by hyperkalemia or hypomagnesemia, but there is wide variation in the severity of the symptoms. Patients may complain of circumoral numbness, paresthesias of the distal extremities, or muscle cramping progressing to carpopedal spasm or tetany. Laryngospasm or bronchospasm and seizures may also occur. Other less specific manifestations include fatigue, irritability, and personality disturbance. Severe hypocalcemia may be associated with a prolonged Q–T interval on electrocardiography, which reverses with treatment. More extensive cardiomyopathic changes are occasionally seen, particularly in adults. These include chest pain, elevated enzymes (CPK), left ventricular impairment, and T-wave inversion, suggestive of a myocardial infarction (143,144). Patients with chronic hypocalcemia may have calcification of the basal ganglia or more widespread intracranial calcification, detected by skull radiograph or CT scan. Also seen are extrapyramidal neurological symptoms (more often with intracranial calcification), subcapsular cataracts, band keratopathy, and abnormal dentition.

Increased neuromuscular irritability may be demonstrated by eliciting a Chvostek or Trousseau sign. The Chvostek sign is prolonged reflex contraction of the facial muscle in response to a digital tap on the cheek just anterior to the ear. As with other hyperreflexias, up to 20% of normal individuals may demonstrate a slight positive reaction. The Trousseau sign is carpopedal spasm induced by inflation of a blood pressure cuff covering the upper arm to 20 mm Hg above systolic blood pressure for 3 min. A positive response reflects the heightened irritability of nerves undergoing pressure ischemia.

In hypoparathyroidism, serum calcium concentrations are decreased and serum phosphate levels are increased. Serum PTH is low or undetectable. (The important exception is PTH resistance—pseudohypoparathyroidism (PHP)—discussed further later.) Usually, serum 1,25(OH)<sub>2</sub>D is low, but alkaline phosphatase activity is normal. Despite an increase in fractional excretion of calcium, intestinal calcium absorption and bone resorption

are both suppressed. The renal filtered load of calcium is decreased, and the 24-h urinary calcium excretion is reduced; nephrogenous cAMP excretion is low and renal tubular reabsorption of phosphate is elevated. After par-enteral administration of biologically active PTH (the Ellsworth–Howard test), the plasma and urinary cAMP, and phosphate excretion increase, differentiating hypoparathyroidism from PHP. However, this test is rarely used in clinical practice now, since diagnosis is more readily established by less invasive means.

Decreased parathyroid gland reserve can be detected by an ethylenediaminetetraacetate infusion study. However, this test is usually not required and should be performed in a metabolic center with careful monitoring and observation.

### 85.15.2 Genetics

Idiopathic hypoparathyroidism is a feature common to a variety of syndromes and inherited disorders. Although most cases are sporadic, familial occurrence is known. This may occur as an autoimmune disorder either alone or with other endocrine deficiencies as in a pluriglandular autoimmune syndrome or associated with diverse developmental abnormalities such as lymphedema, nephropathy, nerve deafness, or cardiac malformation. It also occurs as an isolated finding.

## 85.16 FAMILIAL ISOLATED HYPOPARATHYROIDISM

Familial isolated hypoparathyroidism (FIH) may show autosomal dominant, autosomal recessive, or X-linked inheritance.

In a few instances of autosomal dominant disease, a mutation in the *PTH* gene has been found. In one family presenting reduced hormone production and chronic hypocalcemia, a missense mutation (C18R) in the signal sequence of the preproPTH precursor was identified and the mutant shown to be defective *in vitro* in processing of preproPTH to proPTH, although as patients had one normal gene copy the autosomal-dominant mode of inheritance was unexplained. Further studies in transfected cells showed that the mutant was trapped in the endoplasmic reticulum promoting ER stress and apoptosis (145). In another family, a different mutation in the signal sequence segregated with affected status. This mutation may prevent proper cleavage of the signal peptide during processing of the nascent protein. In one family with autosomal recessive hypoparathyroidism, a donor splice site mutation at the exon 2/intron 2 junction of the *PTH* gene was identified. The mutation leads to exon skipping and loss of exon 2 containing the initiation codon and signal sequence of preproPTH mRNA. In two multigeneration families with X-linked recessive hypoparathyroidism exhibiting neonatal onset of hypocalcemia and parathyroid agenesis, the trait was

mapped to a 906-kb region on distal Xq27 that contains three genes including *SOX3* but no intragenic mutations were found (MIM #307700) (146). A deletion/insertion [del(X)(q27.1)inv ins(X)(q27.1;p25.3)] mutation was identified that was speculated to exert a position effect on *SOX3* expression and affect embryonic development of the parathyroid glands (147).

Gain-of-function mutations in the *CASR* gene have been identified in several families previously diagnosed with autosomal dominant hypocalcemia (ADH) (MIM #601198), autosomal dominant hypoparathyroidism (MIM #241400), and hypocalcemic hypercalciuria (MIM #146200). In the parathyroid gland, the activated *CASR* suppresses PTH secretion and in the kidney, it induces hypercalciuria, which further contributes to the hypocalcemia. In many cases of ADH, a family history is clear, but *de novo* mutations are surprisingly common (148,149). Mosaicism for *de novo* mutation in an otherwise healthy parent has been described (150), and may explain some cases of apparently recessive disease. Importantly, it has serious implications for counseling parents about the risk of recurrence. More than 50 unique activating mutations (almost all missense), of which one-third are recurrent, have been identified, and appear almost equally divided between the amino-terminal third of the ECD and the transmembrane domain (TMD) (Figure 85-2). Of special interest is the cluster of ECD mutations (from A116T to C131W), which cause a leftward (activating) shift in receptor sensitivity, suggesting that this region is critical for receptor activation. This cluster overlaps the two cysteine residues—C129 and C131—involved in the interface of the mature protein dimer. Further details can be found in the locus-specific database—<http://www.casrdb.mcgill.ca/> (3).

Some patients with *CASR*-activating mutations have presented with symptoms of Bartter's syndrome (151,152). Study of these particular mutations confirms that one action of *CASR* in the cortical thick ascending limb is sodium chloride wasting, which can be physiologically tied to increasing losses of calcium and magnesium in the urine.

Parental transmission effects may occur in hypocalcemic disorders associated with activating mutations of the *CASR*, as a result of the maternal–fetal interdependence of calcium metabolism. If affected, a neonate would be at risk for hypocalcemia and seizures during the immediate postnatal period. Conversely, unaffected infants could manifest transient secondary hyperparathyroidism with associated bone demineralization. Therefore, the *CASR* mutational analysis can be useful in monitoring the neonatal course of infants born to a mother with ADH (153).

Recessively inherited FIH may occur with mutations of the glial cell missing-2 gene (*GCM2*; MIM #603716). The *GCM2* gene localizes to chromosome 6p24.2 and encodes a transcription factor. It is expressed in the PTH-secreting cells of the developing parathyroid glands and is critical for their development in terrestrial vertebrates (154–157). In turn, the

transcriptional activator, musculoaponeurotic fibrosarcoma oncogene family B (MafB), that is expressed in the bilateral parathyroid/thymus common primordia is essential for the expression of GCM2 (158). GCM2 transactivates the *CASR* gene promoter (159,160) and in combination with MafB transactivates the *PTH* gene promoter (158). A patient with neonatal hypoparathyroidism was found to be homozygous for a partial deletion of the *GCM2* gene acquired from both parents (161), and a pair of siblings with homozygous mutations has been reported (162). Additional studies have identified other inactivating *GCM2* mutations in cases with autosomal recessive FIH (159,163). On the other hand, heterozygous mutations that cause dominant-negative *GCM2* mutants have recently been identified in patients with autosomal dominant hypoparathyroidism (159,164,165). Nevertheless, it appears that the prevalence of genetic defects affecting *GCM2* function is not high in FIH, as a recent study investigating 20 unrelated cases with this disorder (10 familial and 10 sporadic) failed to identify any *GCM2* mutations segregating with the disease and/or leading to loss of function (166).

## 85.17 HYPOPARATHYROIDISM WITH MULTIPLE MALFORMATIONS

### 85.17.1 DiGeorge and Velocardiofacial Syndromes

Hypoparathyroidism due to parathyroid hypoplasia is a frequent feature of 22q11.2 microdeletions, the common cause of the DiGeorge syndrome (MIM #188400) (167). This syndrome complex arises from a failure of the third and fourth pharyngeal pouches to develop, leading to agenesis or hypoplasia of the parathyroid glands, thymus, and the anterior heart field. Patients with DiGeorge syndrome may typically present with neonatal hypocalcemic seizures due to hypoparathyroidism, severe infections due to thymic hypoplasia, and conotruncal heart defects (168). Because a microdeletion is involved, the identification of novel developmental genes in the 22q11 region has been keenly pursued. Mouse models with *Tbx1* transcription factor haploinsufficiency were used to establish the essential contribution of this factor to conotruncal development (169) and to place it in developmental context during organogenesis (170,171). It is likely, however, that full expression of DiGeorge syndrome involves loss of other contiguous genes (172). Thus, 22q11 deletions are responsible for a wider spectrum of clinical conditions that includes isolated congenital heart disease and velocardiofacial (VCF) syndrome (167). Associated craniofacial abnormalities include cleft palate, pharyngeal insufficiency, and mildly dysmorphic facies. In the VCF syndrome, anatomical anomalies of the pharynx are prominent, and hypernasal speech due to abnormal pharyngeal musculature with or without

cleft palate is typical. In most patients, some degree of intellectual deficit is present and there is a strong predisposition to psychiatric illness (schizophrenia or bipolar disorder) in adolescents and adults (173,174). Further information, both clinical and educational, can be found at web sites devoted to this condition (e.g., <http://www.vcfsef.org/> and <http://www.22q.org/>).

The 22q11.2 defect is one of the most common of microdeletions (1 in 3000 to 1 in 6000 livebirths), and it may go clinically unrecognized in its milder or incomplete forms. Most cases are the result of sporadic new mutations, but familial patterns are evident in up to 10%. Although many cases of DiGeorge syndrome occur *de novo*, autosomal dominant inheritance is not unknown. In utero influences may be important determinants of the clinical picture, since there are instances of monozygotic twins with discordant phenotypes. Phenocopies occur with diabetic embryopathy, fetal alcohol syndrome, and retinoid embryopathy. In rare instances, it has been shown that a phenotypically normal parent can transmit a microdeletion to an offspring. Such parents have been found to carry a duplication of the 22q11 on the second chromosome, and the combination of duplication and deletion alleles in a parent generates a balanced state that has been termed “gene dosage compensation” (175,176).

Although the hypoparathyroidism affects about half of all carriers, it is usually not severe, and frequently treatment following neonatal hypocalcemia can be tapered or stopped in older children. However, the hypoparathyroidism may also remain asymptomatic until adolescence or emerge at times of stress, such as corrective cardiac surgery or severe infection, suggesting that continued surveillance of parathyroid gland reserve is important (177–179).

Currently, diagnosis of 22q11.2 microdeletion requires specific cytogenetic studies—usually with locus-specific FISH testing or PCR-based techniques. These tests reliably pick up many of the larger common deletions that involve regions of low-copy number repeats. However, array-based analyses suggest that 15–30% of microdeletions that are atypical are being missed (167), and it seems likely that microarray methods will eventually become the preferred diagnostic approach. Because the clinical picture is so variable and the prevalence so high, testing for 22q11.2 microdeletion should be considered in the workup for any new hypoparathyroid case for which another cause is not found.

A small but significant minority (~10%) of patients will have associated autoimmune disease, perhaps driven in part, by the thymus-based defect in T cell function (167,180). Among the more common (non-endocrine) conditions are arthritis, celiac disease, and autoimmune hematologic disease, particularly idiopathic thrombocytopenic purpura. Autoimmune thyroid disease, with either hypo- or hyperparathyroid states, has been reported (180,181). It has been suggested that the later-onset hypoparathyroid disease may be partly autoimmune in

origin, not developmental. A survey of 59 Norwegian patients showed discordance of adult onset disease with neonatal hypoparathyroidism, but a significant correlation with parathyroid autoantibodies and the presence of autoimmune disease (180).

### 85.17.2 Barakat/HDR Syndrome

Hypoparathyroidism is a part of the Barakat or Hypoparathyroidism, nerve Deafness, and Renal dysplasia (HDR) syndrome (MIM #146255). Deletions of two non-overlapping regions of chromosome 10p contribute to a DiGeorge-like phenotype (the DiGeorge critical region II on 10p13-14) and the HDR syndrome (10p14-10pter). The latter is due to haploinsufficiency of the *GATA3* gene (MIM #131320), which encodes a dual zinc finger transcription factor (182) that is essential for normal embryonic development of the parathyroids, auditory system, and kidney. Since the original description, several additional *GATA3* loss-of-function mutations have been described in HDR patients (183–185). Heterozygous *Gata3*-deficient mice develop parathyroid abnormalities as revealed when challenged with a diet low in calcium and vitamin D that are due to dysregulation of the parathyroid-specific transcription factor *Gcm2*. *Gata3*<sup>-/-</sup> embryos at E12.5 lack *Gcm2* expression and have gross defects in the third and fourth pharyngeal pouches, including absent parathyroid-thymus primordia (186). *GATA3* transactivates the *GCM2* promoter and with *GCM2* forms part of a transcriptional cascade essential for the differentiation and survival of parathyroid progenitor cells.

### 85.17.3 Kenny–Caffey and Sanjad–Sakati Syndromes

In another congenital disorder, the Kenny–Caffey syndrome, hypoparathyroidism is found variably associated with the typical picture of growth retardation, osteosclerosis, cortical thickening of the long bones, and delayed closure of the anterior fontanel. Both dominant and recessive modes of inheritance have been observed (MIM #127000 and MIM #244460, respectively). The Sanjad–Sakati syndrome (MIM #241410) is a similar recessive condition characterized by congenital hypoparathyroidism, seizures, growth and developmental retardation, and characteristic dysmorphic features, including deep set eyes, depressed nasal bridge with beaked nose, long philtrum, thin upper lip, micrognathia, and large floppy ear lobes. Radiographs show medullary stenosis reminiscent of Kenny–Caffey syndrome. Linkage studies localized recessive Kenny–Caffey and Sanjad–Sakati syndromes to 1q42-43, and causative mutations in the tubulin chaperone E, *TBCE*, gene, were identified in this hypoparathyroidism, retardation, and dysmorphism syndrome (187). This highlighted the role of *TBCE* that binds microtubules and proteasomes and protects against misfolded protein stress (188) in parathyroid development (189).

## 85.18 HYPOPARATHYROIDISM DUE TO METABOLIC DISEASE

### 85.18.1 Mitochondrial Myoneuropathies

Hypoparathyroidism is also a variable component of the neuromyopathies caused by mitochondrial gene defects. Among these are the Kearns–Sayre syndrome (ophthalmoplegia, retinal degeneration, and cardiac-conduction defects) (MIM #530000), the Pearson marrow pancreas syndrome (lactic acidosis, neutropenia, sideroblastic anemia, and pancreatic exocrine dysfunction) (MIM #557000), and mitochondrial encephalomyopathy (MIM #540000). The molecular defects range from large deletions and duplications of the mitochondrial genomes in a number of tissues to single base-pair mutations in one of the transfer RNA genes found only in a restricted range of cell types (MIM #590050). The role of these mitochondrial mutations in the pathogenesis of hypoparathyroidism remains to be clarified, but hypomagnesemia due to renal wasting can present with symptoms similar to hypocalcemia and the two may co-exist in these disorders.

### 85.18.2 Long-Chain Hydroxyacyl-CoA Dehydrogenase Deficiency

Long-chain hydroxyacyl-CoA dehydrogenase deficiency (MIM #600890) is an inborn error of oxidative fatty acid metabolism that may be accompanied by hypoparathyroidism. Whether the parathyroid disease is directly related to the enzyme deficiency or secondary to the accompanying mitochondrial disease needs further study.

### 85.18.3 Inherited Disorders Leading to Metal Storage

Parathyroid insufficiency and symptoms of hypocalcemia are occasionally seen in inherited metabolic disorders leading to excess storage of iron (thalassemia, Diamond–Blackfan anemia, hemochromatosis) or copper (Wilson disease). In most instances, there is similar dysfunction in other endocrine glands, and the parathyroid disease is usually mild. Nonetheless, recognition of the hypoparathyroid state may help explain otherwise nonspecific symptoms and aid in overall management of these multisystem diseases.

## 85.19 AUTOIMMUNE HYPOPARATHYROIDISM: ACQUIRED AND INHERITED DISORDERS

Antibodies directed against parathyroid tissue have been detected in up to 38% of patients with isolated hypoparathyroid disease, and over 40% of patients having hypoparathyroidism combined with other endocrine

deficiencies (190). Subsequently, a survey of a parathyroid expression library led to the identification of one protein selectively associated with the autoimmune process, the NACHT leucine-rich-repeat protein 5 (NALP5). Elevated antibody titers occur in half the patients with autoimmune hypoparathyroidism, with or without other autoimmune disease, but uncommonly in other conditions without hypoparathyroidism (191).

Antibodies against the ECD of the parathyroid CASR were originally reported in more than half of patients with either type 1 autoimmune polyglandular syndrome (APS-1, also known as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy or APECED; MIM# 240300) (192) or acquired hypoparathyroidism associated with autoimmune hypothyroidism. This finding was confirmed in a subsequent study of 51 cases of idiopathic hypoparathyroidism, but there was a 13% positive rate in controls (193). However, larger studies of APS-1 patients failed to reveal a significant preponderance of positives (194–196). Although some have argued that CASR antibody assays are clinically indicated in acquired hypoparathyroidism (197), others have demurred, and it remains to be seen whether the autoantibodies are of primary or secondary importance (190,198). In contrast, there is now good evidence that autoantibodies can be functional activators of CASR and thereby induce hypoparathyroidism (199). Unfortunately, there is no convincing test for this state, outside of an *in vitro* demonstration that patient serum activates CASR transfected into HEK cells. In some hypoparathyroid patients, both autoimmune parathyroid destruction and suppression by CASR activation may co-exist (196).

In APS-1, the most common associated manifestations are hypoparathyroidism with mucocutaneous candidiasis and Addison's disease. Additional features include pernicious anemia, chronic active hepatitis, alopecia, keratitis, gonadal failure, thyroid disease, pancreatic insufficiency, and diabetes mellitus (192). The phenotype is highly variable and patients may not express all elements of the basic triad, leading to the suggestion that the criteria used for molecular screening be relaxed (200). The disease usually presents in infancy with chronic oral thrush, followed by hypoparathyroidism in the first decade, and then adrenocortical failure in the third. Interestingly, there is nearly 100% penetrance of hypoparathyroidism in females, but less than 60% in males, even though the adrenal hypofunction affects both sexes equally (195). Moreover, patients who develop the adrenal hypofunction first are less likely to be male and may never develop hypoparathyroidism. The responsible gene, called the autoimmune regulator (AIRE), maps to chromosome 21q22 and encodes a transcriptional regulator (201). In the absence of AIRE protein, tissue-specific self-antigens are not expressed in the thymus and multiorgan autoimmunity develops, because negative selection of the T cells bearing the autoantigens is disrupted (202). Many patients with APS-1 can be shown to have autosomal

recessive inheritance of the AIRE defect. In families with autosomal recessive mutations of AIRE, obligate heterozygotes may also have common autoimmune disorders but APECED is not seen (203). A phenocopy leading to acquired APS-1 may occur when the AIRE gene is silenced by thymic neoplasia (204). APS-1 has been associated with more than 200 mutations of the AIRE gene, and updates can be found in the online mutation database (<http://bioinf.uta.fi/AIREbase/>).

## 85.20 PSEUDOHYPOPARATHYROIDISM

Several clinical disorders characterized by end-organ resistance to PTH are described collectively by the term pseudohypoparathyroidism (PHP) (205,206). They are associated with hypocalcemia, hyperphosphatemia, and increased circulating PTH, but target tissue unresponsiveness to the hormone manifests as a lack of increased cAMP excretion in response to PTH administration. The biochemical characteristics of these disorders are contrasted with those of hypoparathyroidism in Table 85-8.

### 85.20.1 Albright Hereditary Osteodystrophy

Seventy years ago Fuller Albright first recognized that the likely cause of the hypoparathyroid state in PHP is a constitutive absence of target tissue responsiveness. In many patients, end-organ resistance is accompanied by a specific pattern of physical findings, called Albright hereditary osteodystrophy (AHO). Typically, patients have short stature, round facies, brachydactyly, obesity, and ectopic soft tissue or dermal ossification(s) (osteoma cutis) (Figure 85-5). In the calvaria, this may manifest as hyperostosis frontalis interna (207). Intracranial calcification(s), cataracts and band keratopathy, subcutaneous calcifications, and dental hypoplasia are also common, but are likely to be the consequences of long-standing hypoparathyroid hypocalcemia (Table 85-9). The brachydactyly may be asymmetric or not, and may involve one or both hands or feet, but the pattern is quite distinctive (208,209). The shortening tends to involve the first distal phalanx, leading to a thumbnail (or first toenail) that is wider than it is long. The fourth and fifth metacarpals (or metatarsals) are frequently shortened out of proportion to the others and the second metacarpal is often spared. Radiographic analysis of the hands (pattern profiling) is helpful in assessment of the brachydactyly (see Figure 85-5).

Although affected patients are generally short as adults, their bone age as children may be advanced and growth accelerated. Patients with AHO are probably predisposed to hypertension, conductive and sensorineural hearing loss, cord compression due to spinal anomalies, and movement disorders due to basal ganglia calcification. The features of AHO may be subtle in infancy or early childhood; in a few, there is little to see even in adulthood.

**TABLE 85-8 Biochemical Characteristics of Hypoparathyroidism and Pseudohypoparathyroidism**

	Response to PTH Infusion						Multiple Endocrine Defects
	Serum PO <sub>4</sub>	PTH	25(OH)D	1,25(OH) <sub>2</sub> D	U <sub>cAMP</sub>	U <sub>PO4</sub>

Pseudohypoparathyroidism							
Type 1a	↑	↑	→	↓	↓	↓	Yes
Type 1b	↑	↑	→	↓	↓	↓	No/yes <sup>b</sup>
Type 1c	↑	↑	→	↓	↓	↓	Yes
Type 2	↑	↑	→	↓	→	↓	No

↑, increased; ↓, decreased; →, normal.

<sup>a</sup>Depending upon the etiology.

<sup>b</sup>Variable defects of the thyroid and somatotropin axes are seen.

The round facies, short neck, and low, flat nasal bridge are often accompanied by central obesity. A recent study showed that the obesity phenotype occurs primarily in those patients who also have multiple hormone resistance, that is, PHP1a (see below), but according to data from mice, hypothalamic mechanisms, rather than hypothyroidism, are the primary underlying cause (210).

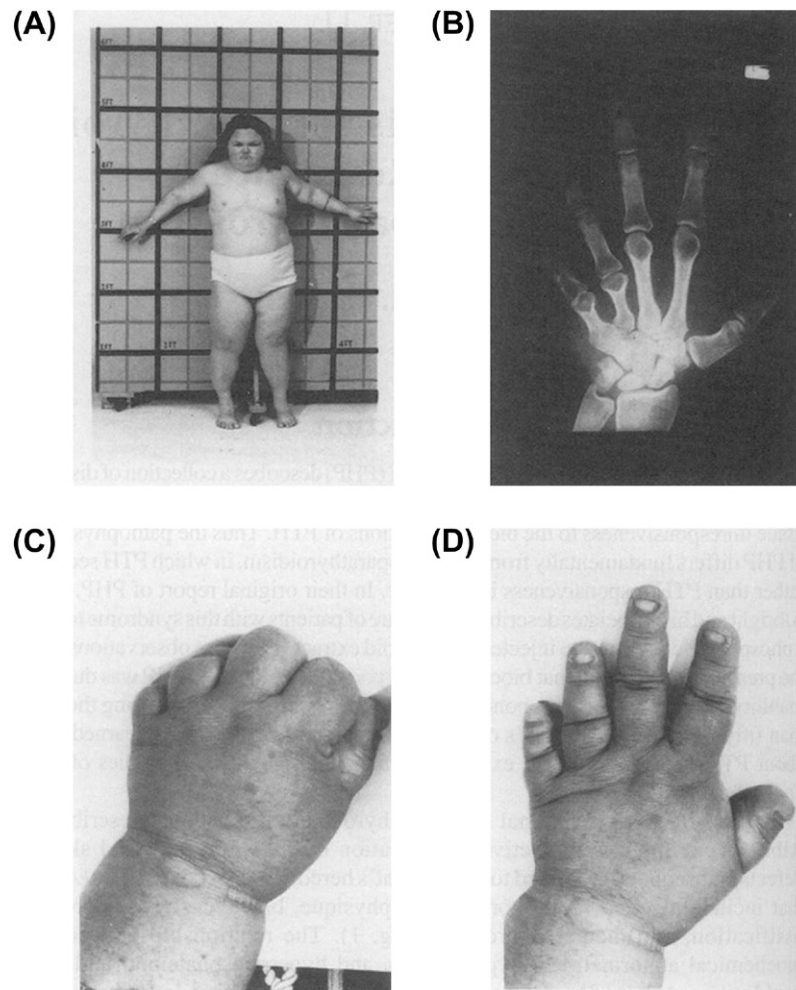

Patients with brachydactyly–mental retardation (BDMR), and other features closely resembling AHO have been found to carry microdeletions of chromosome 2q27 (BDMR; MIM #600430). Genes important for skeletal and neurological development lie within this region. Haploinsufficiency of *HDAC4* (MIM #605314), encoding a histone deacetylase that regulates gene expression during the development of many tissues including the bone, is responsible for the BDMR in those patients (211). Isolated brachydactyly type E (BDE; MIM #113300) has been associated in sporadic cases with mutations in *HOXD13* (MIM #142989) (212), and recently mutations in the *PTHLH* gene (MIM #168470) on 12p11.2 that encodes PTHrP have been implicated. In one family with autosomal BDE, a *cis*-regulatory site downregulates *PTHLH* in translocation t(8;12)(q13;p11.2) and downregulates its targets *ADAMTS-7* and *ADAMTS-12*, leading to impaired chondrogenic differentiation (213). Affected individuals of one large family with BDE, short stature and learning difficulties had an ~900 bp microdeletion encompassing *PTHLH* (214). Additional individuals with BDE and short stature from other different kindreds were found to have missense (L44P and L60P), nonstop (X178WextX\*54), and nonsense (K120X) mutations (214).

### 85.20.2 PHP1a

PHP1a patients, characterized by AHO, PTH resistance, and evidence of target organ resistance to other hormones, are usually found to have a reduction in the activity of the G $\alpha$  subunit, which is part of the membrane-associated heterotrimeric G-protein complex, transducing signals between G-protein coupled receptors and adenylate cyclase. Adenylate cyclase catalyzes the

synthesis of the second messenger cAMP, and, therefore, PHP-1a patients tend to have a deficiency in cAMP generation, particularly in certain tissues (215). This deficiency is clearly evident when measuring cAMP excretion in response to PTH administration.

The *GNAS* gene (MIM #168470) encoding the G $\alpha$  protein maps to 20q13.2-13.3 and has at least four alternative transcriptional start sites (Figure 85-6) and an antisense transcript, *NESPas* (216,217). The three upstream exons and the preceding promoter regions are genetically imprinted, that is, methylated in an allele specific manner. The promoter of the G $\alpha$  transcript, which uses exon 1, is unmethylated. Unlike the other alternative *GNAS* products, G $\alpha$  expression is biallelic with the exception of a small set of tissues, where G $\alpha$  is derived predominantly from the maternal allele (218–220). This tissue-specific monoallelic G $\alpha$  expression affects penetrance of the PHP phenotype. The maternal transmission of the hormone resistance in PHP1a can be explained by silencing of the paternal G $\alpha$  allele, which would otherwise allow expression of 50% of G $\alpha$  protein. Thus, full expression of a coding *GNAS* mutation, which occurs in maternally transmitted cases, leads to AHO plus hormone resistance (PHP1a), whereas a paternally transmitted mutation causes AHO alone (pseudopseudohypoparathyroidism; PPHP) (209). Despite clinical evidence supporting imprinting in portions of the kidney tubule, it has been difficult to confirm this experimentally in humans (221). The imprinting of *GNAS* is complex and involves multiple differentially methylated regions (DMR) (216). Moreover, it is tissue-specific and may vary with developmental stage, although key imprinting of the 1A DMR is a primary event that occurs during gametogenesis and is maintained thereafter (222). Ablation of the G $\alpha$  ortholog in mice (*Gnas*) has confirmed that maternal, but not paternal, transmission of the deleted allele results in PTH resistance. The homozygous deletion of *Gnas* is embryonic lethal. Comparison of G $\alpha$  expression in mice with maternally vs. paternally disrupted G $\alpha$  expression also demonstrated that G $\alpha$  expression is predominantly maternal in the renal cortex, but not in renal medulla.

**FIGURE 85-5** Features of Albright Hereditary Osteodystrophy (AHO). (A) Young woman with short stature (approximately third centile), disproportionate shortening of the limbs, generalized obesity, and round, flattened face. (B) Radiograph of the hand showing the shortened fourth and fifth metacarpals. (C) Fist with the characteristic “dimples” over the third, fourth, and fifth digits replacing the knuckles formed by the distal head of normally sized metacarpal bones (Archibald sign). (D) Brachydactyly of the hand, with the short fourth and fifth digits, the greatly foreshortened terminal first digit, and very short, wide thumbnail (potter’s thumb). (From Levine, M. A. In *The Genetics of Osteoporosis and Metabolic Bone Disease*; Econs, M. J., Ed.; Humana Press: New York, 2000; pp 179–209.)

A variety of inactivating mutations in the portion of the *GNAS* gene encoding  $G\alpha$  have been identified in PHP1a patients (223,224). The spectrum includes missense mutations, point mutations impairing efficient and accurate splicing, and small insertion/deletion mutations. A 4-bp deletion in exon 7 ( $\Delta$ GACT 188/190) has been observed in multiple unrelated cases, suggesting that this may be a hot spot (223). Several other mutations have also been observed in more than one kindred, indicating that additional susceptibility regions may exist. The identification of de novo germline mosaicism (225) is consistent with the view that most sporadic cases harbor new mutations, but the separation of such sporadic cases from familial ones, in which there is suppression of phenotype due to imprinting, may be difficult without detailed molecular studies.

PHP1a cases have been described in which no mutations of the *GNAS* gene have been found by nucleotide sequence analysis of exons encoding  $G\alpha$ . This may be

because the mutation is in a regulatory region of the gene not yet examined, or it may be that a large deletion prevents amplification of the mutant allele for subsequent analyses. In cases without identified *GNAS* coding mutations, an assessment of  $G\alpha$  bioactivity in erythrocytes is helpful in ruling out regulatory region mutations or large deletions. A 30-kb deletion spanning exons 1–5 has been identified recently by using comparative genome hybridization in a patient with PHP1a in whom coding mutations had been ruled out but a marked reduction of erythrocyte  $G\alpha$  activity demonstrated (226,227). Typically, PHP1a is associated with multiple hormone resistance, including thyroid stimulating hormone (TSH) and gonadotropins, causing hypothyroidism and gonadal failure, respectively. Because the hypothyroidism may express before hypocalcemia is observed, early surveillance of thyroid function is warranted. However, thyroid replacement from birth does not appear to prevent the mental deficit typical of PHP1a. In women, the

<sup>a</sup>Features common to other forms of chronic hypoparathyroid hypocalcemia. Taken from Drezner, M. K.; Neelon, F. A. Pseudohypoparathyroidism. In *The Metabolic Basis of Inherited Disease*; Scriver, C.R., Beaudet, A. L., Sly W. S., Valle, D., Eds.; McGraw-Hill: New York, 1995, pp 1508–1527.

hypogonadism is partial so that oral contraceptives may help regulate the menstrual cycle. Estrogen can antagonize bone resorption leading to an exacerbation of hypocalcemia, but placental 1,25-(OH)<sub>2</sub>D synthesis likely obviates this effect altogether in pregnancy, so women are frequently normocalcemic at that time. Abnormalities of the somatotropin axis have also been reported, with documentation of subnormal growth hormone release following stimulation by L-arginine or growth hormone releasing hormone (228,229). The effect of growth hormone replacement has been recently investigated in a small group of pre-pubertal PHP-1a patients (230). This study concluded that the treatment is potentially effective but has to be initiated as early as possible. The tissue-specific silencing of the paternal *Gsα* allele also plays a key role in the development of the additional hormone resistance phenotypes, as monoallelic *Gsα* expression has been demonstrated in the thyroid, the ovaries, and the pituitary (218–220,231). Recent studies have revealed that obesity also develops primarily in patients who inherit the inactivating *Gsα* mutations from their mothers (232). *Gsα* is not imprinted in the white adipose tissue (233), but the investigations of mice in which *Gsα* is ablated conditionally in the brain showed that *Gsα* is also monoallelic in certain parts of the hypothalamus (210), thus explaining the imprinted mode of inheritance of the obesity phenotype. Likewise, it has been recently noted that cognitive impairment, a typical AHO feature, also develops primarily after maternal inheritance of the inactivating *Gsα* mutation (234).

### 85.20.3 PHP1b

PHP1b is typically not associated with AHO or a generalized reduction in *Gsα* expression. PHP1b patients show a defect in renal PTH signaling, but an apparently normal response to PTH in bone. Affected individuals are, therefore, functionally hypoparathyroid but show normal skeletal architecture and development. Due to unimpaired PTH responsiveness in bone, signs of hyperparathyroid bone disease (osteitis fibrosa cystica) are occasionally observed, complicating the picture. Biochemical abnormalities suggestive of TSH resistance are also seen in some patients (231), and abnormalities of renal uric acid handling have been documented (235,236). Because the hormone resistance is mostly limited to PTH, it was thought at one time that these findings could be explained by a defect in the type-1 parathyroid hormone receptor (*PTHR1*, MIM #168468), but sequencing in PHP1b patients shows no mutations in protein-coding exons or gene promoter regions of the gene, and studies of PHP1b families show no linkage to *PTHR1*.

Most cases of PHP1b are sporadic, but a familial form of PHP-1b with an apparent autosomal dominant mode of inheritance also exists (AD-PHP-1b). In four AD-PHP1b kindreds, linkage to chromosome 20q13.3 was established, the same region which includes the *GNAS* locus. In these families, the pattern of transmission suggests paternal imprinting, and inheritance is therefore the same as for PHP1a (217). Another 13 PHP1b subjects, some of whom had bone responsiveness to PTH, were studied. All lacked methylation of the alternate exon 1A (also known as A/B), an epigenetic defect that is postulated to inhibit expression of the functional exon 1-containing *Gsα* transcript in renal tissues only (Figure 85-6). Thus, the loss of methylation of the maternal as well as paternal *Gsα* alleles, causing PTH resistance specifically in renal proximal tubule cells (222). Genetic analysis indicated that mutations in a regulatory region some distance from the *GNAS* coding exons were likely to account for the unique imprinting defect(s) associated with PHP1b (237). A search for the mutation revealed the presence of a 3-kb microdeletion that segregated with the disease in 12 kindreds with AD-PHP1b and also occurred in four sporadic cases (238). The deletion, flanked by direct repeats, removes three exons of the *STX16* gene which encodes syntaxin-16 (Figure 85-7). In addition, another deletion within *STX16* that removes exons 2–4 was later identified in a single kindred with AD-PHP1b (239). In all these cases, maternal, but not paternal, inheritance of the *STX16* deletion led to PTH resistance. Because *STX16* is apparently not imprinted (239), loss of one copy of this gene is not predicted to underlie the PHP1b pathogenesis. Instead, these deletions presumably disrupt a *cis*-acting element that controls imprinting at *GNAS* exon 1A. In two other PHP1b kindreds, nearly identical deletions of the NESP55 DMR

**FIGURE 85-6** The normal allele-specific methylation and expression patterns of the four alternate first exons of *GNAS*, which splice onto exon 2 to produce transcripts encoding NESP55 (NESP),  $XLaS$ , a transcript of unknown function (exon 1A), and  $Gs\alpha$  (exon 1). NESP55 and  $XLaS$  promoters are oppositely imprinted: NESP55 is expressed from the maternal allele and its promoter region is methylated on the paternal allele, whereas  $XLaS$  is expressed from the paternal allele and its promoter is methylated on the maternal allele. The  $XLaS$  promoter also generates paternally expressed antisense transcripts, and the first antisense exon is shown (NESPas). Exon 1 appears to be paternally imprinted in some tissues (e.g., renal proximal tubule cells) indicated by the dashed arrow. NESP55 protein is unrelated to  $Gs\alpha$ , and its entire coding region is located within its first exon. In contrast,  $XLaS$  and  $Gs\alpha$  proteins have identical COOH-terminal domains (encoded by exons 2–13), while their unique NH<sub>2</sub>-terminal domains are encoded within their respective first exons. Exon 1A does not have a translational start site. It is proposed that loss of exon 1A imprinting leads to decreased  $Gs\alpha$  expression in renal proximal tubules and is the cause of PHP1b. (From Liu, J., et al. *GNAS: Normal and Abnormal Functions*. Endocrinology. 2004, 145, 5459–5464.)

including exons 3 and 4 of the antisense transcript segregated with the disease (240). In this instance, however, the 1A DMR was not the only region to lose the differential methylation required to allow maternal expression of  $Gs\alpha$  in the kidney. Maternal methylation was also lost in the regions of the  $XLaS$  and NESPas promoters. Another kindred with these widespread epigenetic defects of *GNAS* has recently been described (241). The affected individuals in this kindred carried a maternally inherited deletion that removed antisense exons 3 and 4 with flanking intronic regions but not the NESP55 exon.

Sporadic PHP1b cases also show broad *GNAS* epigenetic defects that involve exon 1A (242). In some of these cases, paternal uniparental disomy of different chromosome 20 segments have been reported as the likely cause of PHP1b (243–246). The cause of the epigenetic defects and PTH resistance, however, remains unknown for most cases of sporadic PHP1b. Based on one report, no marked clinical differences could be established according to the pattern of *GNAS* epigenetic defects, although serum PTH levels were significantly higher in females with broad *GNAS* methylation defects than females with isolated loss of 1A methylation (247).

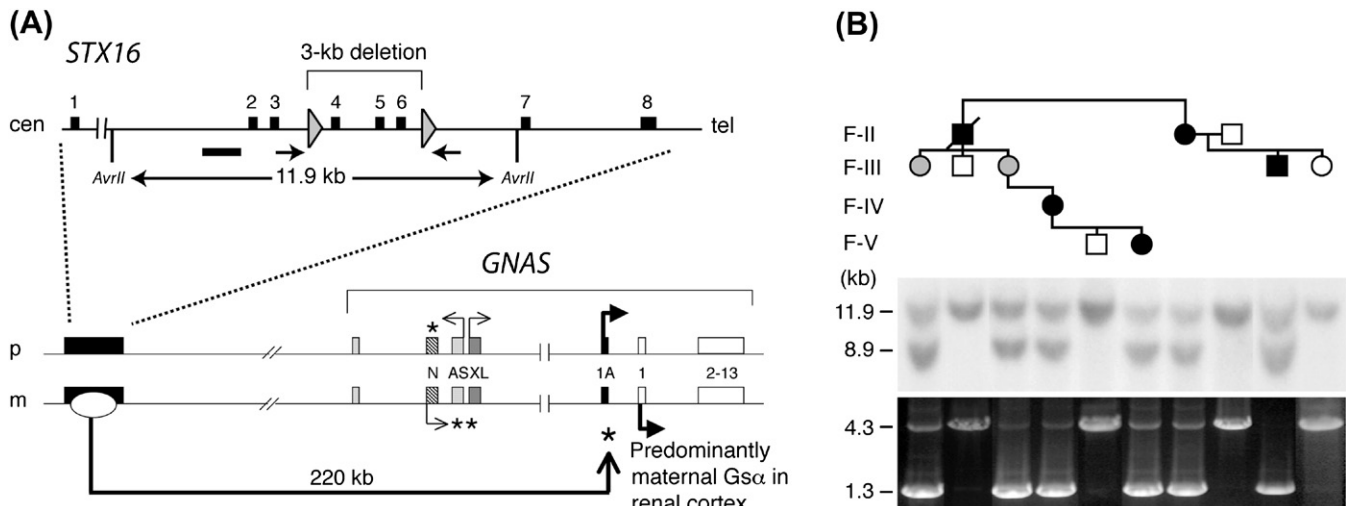

In contradistinction to the classical understanding that AHO features are unique to PHP1a, some recent studies have identified patients with PTH resistance and AHO features who show *GNAS* epigenetic defects rather than  $Gs\alpha$  coding mutations (226,248,249). Thus, there may be some overlap between the clinical and molecular features of PHP1a and PHP1b. It is possible that the AHO features observed in patients with *GNAS* epigenetic defects result from a genetic mechanism that is similar to the mechanism underlying the hormone resistance in PHP1a patients, that is, due to monoallelic  $Gs\alpha$  expression in additional tissues.

A PHP1b family with a novel  $Gs\alpha$  mutation, deletion of isoleucine-382 in the carboxyl terminus (leading to uncoupling from the PTHR and isolated PTH resistance), shows transmission through three generations, consistent with paternal imprinting (250). However, such mutations within  $Gs\alpha$  coding exons are rare.

#### 85.20.4 PHP1c and PHP2

Patients with PHP1c have multiple hormone resistance but normal  $Gs\alpha$  activity. The defect may be in other components of the receptor-adenylate cyclase system, such as the catalytic unit, but some PHP1c cases have been reported to carry  $Gs\alpha$  coding mutations (251). These mutations render the  $Gs\alpha$  protein unable to mediate cAMP generation in response to receptor activation but do not affect basal adenylate cyclase stimulating activity or the ability to be activated by non-hydrolyzable GTP analogs (251–253). Thus, some forms of PHP1c appear to be an allelic variant of PHP1a. Finally, patients with PHP2 have a normal urinary cAMP response to PTH but an impaired phosphaturic response. The defect could be in the cAMP-dependent protein kinase (PKA), one of its substrates or targets, or in a component of the PTH-PKC signaling pathway.

A recent study (254) has discovered a heterozygous mutation of the gene encoding the regulatory subunit of PKA (*PRKAR1A*) in three patients with multiple hormone resistance and acrodysostosis (MIM #101800), a form of skeletal dysplasia that includes severe brachydactyly and other skeletal findings that resemble AHO. This mutation (p.R368X), which leads to the truncation of the COOH-terminal 14 residues, impairs cAMP binding to the regulatory subunit, thereby blocking the activation of PKA (254). In addition to acrodysostosis, patients carrying this mutation display evidence for target organ resistance to PTH, thyrotropin, growth

**FIGURE 85-7** (A) The syntaxin-16 (*STX16*) gene, which is not imprinted, is located some 220 kb upstream of *GNAS* exon 1A. A heterozygous 3 kb deletion that is flanked by two direct repeats of 391 bp (triangles), within the maternal *STX16* gene, is hypothesized to disrupt a putative element that controls the normal establishment and/or maintenance of exon 1A methylation. The epigenetic change and/or associated derepression of maternal 1A transcript expression is postulated to silence maternal *Gsα* protein expression in renal proximal tubule cells. N, NESP55; AS, antisense; \*, normally methylated. (B) Identification of the 3-kb microdeletion in a PHP-1b kindred. (Top) Filled symbols, affected individuals; open symbols, healthy individuals; gray symbols, unaffected obligate gene carriers. (Middle) Genomic DNA digested with *AvrII* and subjected to Southern blot analysis. The position of *AvrII* sites flanking the normal restriction fragment of 11.9 kb and of the probe is indicated in Panel A. (Bottom) PCR amplification of wild-type (4.3 kb) and mutant (1.3 kb) alleles from genomic DNA. (Redrawn from Bastepe, M., Frohlich, L. F., Hendy, G. N., et al. Autosomal Dominant Pseudohypoparathyroidism Type 1b Is Associated with a Heterozygous Microdeletion That Likely Disrupts a Putative Imprinting Control Element of *GNAS*. *J. Clin. Invest.* 2003, 112, 1255–1263.)

hormone releasing hormone, and gonadotropins, but these findings are accompanied by elevated basal plasma and urinary cAMP levels and with an apparently normal urinary cAMP response to exogenous PTH administration.

### 85.21 OTHER PHENOTYPES ASSOCIATED WITH *GNAS* MUTATIONS

In contrast to the PHP phenotype associated with inactivating *GNAS* mutations, a different form of sporadic bone disease, (polyostotic) fibrous dysplasia, results from de novo *GNAS* mutations that cause constitutive *Gsα* activity (255). A more severe form of this disease (panostotic fibrous dysplasia) with hyperphosphatasia and hyperphosphaturic rickets has also been described. Patients carrying these activating mutations are mosaic for mutant and wild-type cells, indicating that the mutation is acquired during postzygotic development. These mutations affect the arginine residue at position 201 (exon 8) and, rarely, the glutamine at 227 (exon 9), and inhibit the intrinsic GTP hydrolase activity of *Gsα* and, thereby, lead to constitutive activity. Such constitutively activating mutations of *GNAS* are also found in a variety of endocrine and non-endocrine tumors, such as growth hormone-secreting adenomas. A missense mutation in exon 13 (A366S) results in a *Gsα* protein that is unstable at 37°C, but constitutively active at lower temperatures. Affected patients have PHP due to PTH resistance and precocious puberty (testitoxico-sis) due to hormone-independent constitutive activation

of luteinizing hormone receptors at lower ambient temperatures in the testes. Another *Gsα* mutant carrying Ala-Val-Asp-Thr amino acid repeats in the guanine-binding domain has been recently described in a patient with neonatal diarrhea and PTH resistance (256). In this instance, the mutant protein is unstable and localized to the cytoplasm rather than plasma membrane, which explains the hormone resistance. On the other hand, this mutation increases the rate of GDP–GTP exchange and, thus, confers overactivity. The increased activity of *Gsα* seems to be evident during the neonatal period in the gut, where the mutant localizes to the plasma membrane, thus explaining the diarrhea phenotype. Undoubtedly, other patterns of altered hormone–receptor interaction due to a *GNAS* mutation await discovery.

Inactivating *GNAS* mutations have also been identified in patients with congenital osteoma cutis and progressive osseous heteroplasia (POH), suggesting that these connective tissue conditions are another variant in the phenotypic spectrum of *GNAS*-related disease (257). No genotype–phenotype correlation has been revealed regarding these disorders, as the same mutation can be associated with either typical AHO features or severe ossifications that involve deep connective tissues and skeletal muscle (258). Nonetheless, most patients with POH inherit the *GNAS* mutation from their fathers or acquire this mutation de novo on the paternal *GNAS* allele. This parent-of-origin-specific inheritance of POH was established by analyzing 18 unrelated kindreds with this disorder (259). In a single three-generation kindred, the inheritance of the mutation from males led to POH,

while the inheritance of the same mutation from females led to typical AHO. It thus appears likely that alterations in the activity of a paternally expressed *GNAS* product, such as XL $\alpha$ s, contribute to the pathogenesis of POH.

### 85.21.1 Differential Diagnosis and Genetic Counseling

Patients with dysmorphic features resembling AHO may require careful endocrinologic workup to confirm and delineate the form of PHP that is present. Similar studies of family members may also be warranted, since the biochemical and clinical features vary within families. If PHP1a with AHO is established, genetic counseling may aid in understanding the multisystemic nature of the disorder, particularly in relation to the patient's growth and development, and later-onset connective tissue complications. For either PHP1a or PHP1b, extensive counseling may be required to adequately explain the various implications of paternal imprinting for the parent-specific recurrence risks in offspring. Germline mosaicism has been reported (224), which is clearly important in assessing risks for recurrence in future sibs of a singleton family. Given the recently described complexities in the molecular, biochemical, and physical features of PHP1a and PHP1b, molecular testing is critical for achieving a clear diagnosis and validating the inheritance pattern in any given family.

## 85.22 THE PARATHYROID HORMONE RECEPTOR AND SKELETAL DYSPLASIAS

Polymorphisms in the *PTHr1*, MIM #168468, are associated with adult height and BMD (260), emphasizing the role that the receptor and its ligands play in endochondral bone formation. Inactivating or loss-of-function mutations in the *PTHr1* have been implicated in the molecular pathogenesis of Blomstrand's lethal chondrodysplasia (BLC, MIM #215045) and other skeletal dysplasias and dental abnormalities (140). The rare BLC disease is characterized by advanced endochondral bone maturation, short-limbed dwarfism, abnormal breast and tooth morphogenesis, and fetal death, thus mimicking the phenotype of *Pthr1*-less mice. The majority of BLC cases were born to phenotypically normal consanguineous parents suggesting an autosomal recessive mode of inheritance. Mutant *PTHr1*s identified in BLC fetuses (Figure 85-4) fail to bind ligand or stimulate cAMP or inositol phosphate production. The Blomstrand disease has been recently subdivided into type I, which refers to the severe (classical) form, and type II, which refers to a relatively milder variant, and the difference between severities is attributed to complete or incomplete inactivation of the *PTHr1*, respectively (261,262). A milder form of recessively inherited skeletal dysplasia, known as Eiken's syndrome (MIM #600002), has been linked to mutations of *PTHr1* (263), suggesting a wider range

of skeletal phenotypes to this gene. Dominantly acting heterozygous *PTHr1* mutations have been identified in endochondromas of patients with endochondromatosis (Ollier's disease, MIM #166000), a familial disorder with evidence of autosomal dominance characterized by multiple benign cartilage tumors, and a predisposition to malignant chondrosarcomas (264,265). As many patients with Ollier's disease do not apparently have *PTHr1* mutations, the condition may be genetically heterogeneous (266). Dominantly inherited symmetrical enchondromatosis is associated with duplication of 12p11.23 to 12p11.22 that includes the *PTHr1* gene encoding PTHrP, suggesting that abnormal *PTHr1* signaling may underlie this unusual form of endochondromatosis (267). In addition, some cases of autosomal dominant nonsyndromic primary failure of tooth eruption (PFE) are due to loss-of-function mutations in the *PTHr1* that are dominantly acting leading to haploinsufficiency of the receptor (268,269).

## 85.23 NHERF1 MUTATIONS AND RENAL RESPONSIVENESS TO PARATHYROID HORMONE

In the renal proximal tubule, the sodium–hydrogen exchanger regulatory factor 1 (NHERF1) bridges the *PTHr1* and sodium phosphate cotransporter, NPT2a. In a group of patients with nephrolithiasis or bone demineralization, three mutations in NHERF1 were found in seven patients with low tubular maximal reabsorption of phosphate over glomerular filtration rate (TmP/GFR) (270). In cultured renal cells, the mutants demonstrated increased cAMP production and reduced phosphate transport in response to PTH.

## 85.24 HYPOMAGNESEMIA

In humans, hypomagnesemia leads to a suppression of PTH release and some degree of peripheral resistance. Although the exact molecular mechanism underlying the suppression of the parathyroid gland in hypomagnesemia is unknown, it is important to recognize that laboratory testing in cases of hypocalcemia with reduced PTH should include measurement of serum magnesium, particularly in newborns (271).

## 85.25 MANAGEMENT OF HYPOPARATHYROIDISM

### 85.25.1 Calcium and Vitamin D

The goal of treatment in hypoparathyroid states is to raise the serum calcium sufficiently to alleviate acute symptoms of hypocalcemia and prevent the chronic complications (142). The calcium concentration required for this purpose is generally the low–normal range. Acute or severe symptomatic hypocalcemia is best treated with

intravenous calcium infusion. Initial doses of 2–5 mM of elemental calcium as the gluconate salt can be given over a 10- to 20-min period, followed by 2 mM elemental calcium per hour as a maintenance dose, to be adjusted according to symptoms and biochemical response. Care must be taken to ensure that the infusion does not extravasate, and ionized or total calcium levels should be monitored frequently on a stat basis. Doses in children 5–14 years of age need to be adjusted for body weight, while neonates and infants require age-specific dosing schedules. In adults, intravenous vitamin D therapy is not needed. Hyperphosphatemia, alkalosis, and hypomagnesemia should be corrected concomitantly if present. Post-surgical hypocalcemia is now rarely severe and usually transient with appropriate management (272). However, the occasional patient can represent a significant problem, particularly if the indication for surgery is chronic hyperparathyroidism, and the post-operative hypoparathyroid state is permanent (273). The long-term effects of standard therapy remain a concern (274).

The mainstay of chronic treatment is oral calcium and vitamin D, which should be started as soon as possible to allow reduction and discontinuation of the intravenous calcium. Oral calcium comes in several forms, but calcium carbonate is generally the least expensive. A total of 20–80 mM elemental calcium daily (2–8 g calcium carbonate per day) is generally effective, but should be given in divided doses and adjusted on the basis of gastro-intestinal tolerance, relief of hypocalcemic symptoms, and appropriate biochemical response. Vitamin D is preferably administered as calcitriol (0.25–1.0 mg per day) but, if cost is a factor, pharmacological doses of cholecalciferol or ergocalciferol or calcidiol may be less expensive and equally efficacious. Cholecalciferol and ergocalciferol have the longest duration of action and can result in sustained toxicity. It is, therefore, appropriate to institute a starting dose of 25,000 IU/day and titrate upward (to 100,000 IU/daily) with assessment of serum and urinary parameters afterward with follow-up at 6 and 12 months, even if the patient is relatively asymptomatic. In any event, serum calcium and 24-hour urinary excretion should be carefully monitored when therapy is started and continued until the patient is stabilized. Hypercalciuria that occurs as treatment is initiated, even prior to the normalization of the serum calcium, may warrant an ongoing assessment of nephrocalcinosis, most sensitively detected by renal ultrasound. Consequently, only a low-normal serum calcium may be attainable, but many patients feel well enough that there is no need to entirely normalize the serum calcium. That way, the risk of renal failure due to chronic hypercalciuria—especially problematic in patients with CASR activating mutations (148)—is minimized. Nevertheless, a significant number of patients report problems with easy fatigue and exhaustion, and mood disturbances (e.g., depression, anxiety, hostility, and paranoid ideation) not in keeping with the degree of hypercalcemia, suggesting

that there may be non-calcitropic effects of PTH not remedied by maintenance of normocalcemia alone (274).

In PHP, monitoring serum PTH levels during treatment is critical with the aim of normalizing or reducing PTH levels as much as possible. This is done to avoid the long-term elevation of circulating PTH, that would likely cause bone resorption. Also, hypercalciuria as a result of the calcitriol and calcium treatment is a lesser concern because PTH actions in the distal tubule are functional, preventing the loss of calcium in the urine. Of note, calcitriol (and not other forms of vitamin D) should be used for the treatment, because the PTH resistance in the proximal tubule does not allow for the efficient synthesis of 1,25(OH)<sub>2</sub>D from 25-hydroxyvitamin D.

### 85.25.2 Hormone Replacement Therapy

Hormone replacement has been advocated as a potentially superior form of treatment for decades but only recently have preparations of recombinant human hormone—teriparatide (PTH 1-34) and full length parathyroid hormone (PTH 1-84)—become widely available. Preliminary studies on 27 adults suggested that hypercalciuria was less of a problem in hypoparathyroid subjects receiving twice daily subcutaneous injections of PTH 1-34 (275). Similar trials have been reported in hypoparathyroid children, with a reduction in calcitriol requirements (276,277). Teriparatide administered every other day in hypoparathyroid adults has been shown to reduce calcium and calcitriol requirements over a 24-month period (278), while PTH 1-84 is associated with a reversal in abnormal bone remodeling, without major adverse effects (279). Although both hormonal agents are well tolerated acutely, long-term exposure of animals to very high doses has been associated with tumor formation (280). While there is no evidence of increased risk associated with replacement doses, caution has been advised particularly in children. In hypoparathyroidism due to activating CASR mutations, such potential risks need to be balanced against ongoing risks of progressive renal damage associated with excessive hypercalciuria, exacerbated at times by the standard calcium and vitamin D therapy. Although the evidence is limited, it appears that hormone replacement is a safe and beneficial option in some of the affected children (281,282). However, better criteria for recommending a switch to recombinant human hormone use are needed, along with more data on long-term safety (283).

### 85.25.3 Calcilytics

Calcilytics—drugs that antagonize the CASR and promote PTH secretion—are a promising alternative for disorders with intact but hypofunctioning parathyroid glands (284). When administered to healthy adults, the CASR antagonist, ATF936, causes a dose-dependent rise in serum PTH immunoreactivity that constitutes proof

of principle (285), but studies have not been reported in hypoparathyroid subjects.

### 85.25.4 Other Therapies

If the serum calcium attainable with oral calcium and calcitriol is below the normal range and the patient remains symptomatic, then a trial of a thiazide diuretic may be considered, with the aim of reducing the hypercalciuria to raise the serum calcium further. The argument for efficacy seems greatest for responsive forms of autosomal dominant hypocalcemia due to activating CASR mutations, since the thiazide-sensitive transporter, SLC12A3 (MIM #600968), is a downstream target for suppression by activated CASR in the kidney. For reasons that are not clear, however, thiazides work well in some patients (286) but not others.

As the serum calcium is normalized, elevated serum phosphate concentrations generally decline but phosphate-binding gels such as aluminum hydroxide are occasionally helpful in reducing hyperphosphatemia at the beginning of therapy.

Patients with intracranial calcifications may experience seizures related to chronic neuropathic changes and it may be necessary to add appropriate anti-epileptic medication(s). In all chronically hypocalcemic patients, ocular assessments should be performed periodically.

### 86.1 INTRODUCTION

Diabetes mellitus is a diagnostic term for a group of disorders characterized by abnormal glucose homeostasis resulting in elevated blood sugar. There is variability in its manifestations, wherein some individuals have only asymptomatic glucose intolerance, while others present acutely with diabetic ketoacidosis, and still others develop chronic complications such as nephropathy, neuropathy, retinopathy, or accelerated atherosclerosis. It is among the most common of chronic disorders, affecting up to 5–10% of the adult population of the Western world. Its prevalence varies over the globe, with certain populations, including some American Indian tribes and the inhabitants of Micronesia and Polynesia, having extremely high rates of diabetes (1,2). The prevalence of diabetes is increasing dramatically and it has been estimated that the worldwide prevalence will increase by more than 50% between the years 2000 and 2030 (3).

It is clearly established that diabetes mellitus is not a single disease but a genetically heterogeneous group of disorders that share glucose intolerance in common (4–7). The concept of genetic heterogeneity (i.e. that different genetic and/or environmental etiologic factors can result in similar phenotypes) has significantly altered the genetic analysis of this common disorder. Diabetes and glucose intolerance are not diagnostic terms, but, like anemia, simply describe symptoms and/or laboratory abnormalities that can have a number of distinct etiologies.

### 86.2 DIFFICULTIES IN GENETIC STUDIES OF DIABETES

The geneticist is confronted with a number of obstacles in attempting to unravel the genetics of diabetes. These include differences in the definition of affected

individuals, modification of the expression of the diabetic genotype by environmental factors, and variability in the age of onset of the disease. One of the major sources of confusion in the study of diabetes mellitus has been the definition of an “affected” individual. Some investigators have called an individual diabetic only if they have clinical symptoms of the disease, whereas others have accepted a mildly abnormal glucose tolerance test. There is marked clinical variability in diabetes. The phenotypic expression of the diabetes genotype (or genotypes) appears to be modified by a variety of environmental factors, including diet, obesity, infection, and physical activity, as well as sex and parity. Obese individuals with type 2 diabetes may lose all signs of the disorder, clinical as well as chemical, if their weight returns to normal. Because of the marked variability in the age of onset of the disease, at any given time only a fraction of those individuals possessing the diabetic genotype may be recognized. Therefore, it may be impossible to say at any specific time whether a clinically unaffected individual carries the diabetic genotype. Thus, longitudinal studies are required to detect those genetically affected family members who will eventually manifest clinical disease.

The high prevalence of diabetes in the population presents additional difficulties for the geneticist. Are relatives affected because they have the same genotype, because they share the same environment, or because they have a chance occurrence of a common disorder? Furthermore, the diabetic syndromes are sufficiently common that two genetically different forms may occasionally occur in the same family. The most important impediment to genetic analysis has been a lack of knowledge concerning the basic defect(s) in each of the disorders leading to diabetes. Because of this, there is no certain method for detecting all individuals with disease-predisposing genotypes

before their clinical manifestations, that is, individuals who possess the diabetic genotypes but have no signs of abnormal carbohydrate metabolism. Despite all these obstacles, major strides have been made in delineating the genetic basis of the diabetic syndromes. The main force behind these advances has been genome-wide association studies (GWAS) conducted in thousands to tens of thousands of subjects, typically in cross-sectional case/control cohorts, targeting either type 1 or type 2 diabetes. Such large sample sizes have been able to overcome clinical heterogeneity and have yielded dozens of susceptibility loci for both forms of diabetes.

## 86.3 DIABETES IN FAMILIES AND TWINS

### 86.3.1 Familial Aggregation of Diabetes

Many authors have shown that diabetics have an “increased family history” of the disease (4). In most reports, the frequency of diabetics with positive family histories of the disease ranges from 25% to 50%. Since the frequency of a positive family history of diabetes in nondiabetic individuals has usually been found to be below 15%, this family history information has been used to support the hypothesis that diabetes mellitus is a hereditary disorder. These types of data, however, are not very powerful. A more accurate method of assessing familial aggregation is to compare diabetes prevalence in specific relatives of affected individuals with that found among similar relatives of nondiabetic controls. Pincus and White (8) were the first to use this method in the study of diabetes, when they statistically established the increased prevalence of the disease among the relatives of diabetics. These findings have since been confirmed by many other investigators (4). Using more sensitive markers of the diabetic genotype, such as oral, intravenous, and cortisone-induced glucose tolerance tests, it has been found that the prevalence of affected individuals among the relatives of diabetics is even higher (usually ranging between 10% and 30% of the parents, sibs, or close relatives, as compared to a prevalence of 1–6% of the relatives of nondiabetic individuals). Thus the prevalence of both clinical diabetes and abnormal glucose tolerance is significantly greater among the close relatives of diabetics than among similar relatives of nondiabetic individuals.

### 86.3.2 Early Twin Studies

Familial aggregation of a trait may be caused by either genetic or environmental factors and twin studies have been used to confirm the importance of genetic factors in the etiology of diabetes. Using clinical diabetes as the criteria for affected, most investigators have reported a concordance rate for monozygotic (MZ) twins between 45% and 96% and for dizygotic twins between 3% and 37%. When type 2 diabetes is considered separately

and glucose tolerance tests are performed in the “non-diabetic” MZ cotwins, the concordance rate is usually above 70%. Thus the concordance of diabetes mellitus in MZ twins is significantly greater than in dizygotic twins, suggesting an important genetic component to disease etiology. The available data suggest that dizygotic twin risk appears to be approximately equivalent to that of siblings, arguing that whatever environmental factors contribute are present in the majority of a given population and suggesting that there is not a large contribution from unique family environments. As will be discussed later, the MZ concordance rates are very different for type 1 and type 2 diabetes.

## 86.4 GENETIC HETEROGENEITY IN DIABETES

Although the evidence from studies of familial aggregation and twins leaves no doubt as to the importance of genetic factors in the etiology of diabetes, for many years there was little agreement as to the nature of the genetic factors involved. This confusion can, in large part, be explained by the genetic heterogeneity that is now known to exist in diabetes. In 1967, the hypothesis of genetic heterogeneity was proposed based on several lines of evidence. Indirect evidence included (1) the existence of distinct, mostly rare genetic disorders (now numbering over 80) that have glucose intolerance as one of their features; (2) genetic heterogeneity in diabetic animal models; (3) ethnic variability in prevalence and clinical features; (4) clinical variability between the thin, ketosis-prone, insulin-dependent juvenile onset diabetic (type 1) and the obese, nonketotic insulin-resistant adult-onset diabetic (type 2); and (5) physiological variability (i.e. the demonstration of decreased plasma insulin in juvenile versus the relative hyperinsulinism of maturity-onset diabetics). In addition, some direct evidence for heterogeneity came from clinical genetic studies that suggested that juvenile and adult-onset diabetes differed genetically within families (9).

### 86.4.1 Rare Syndrome Associations

There are more than 80 distinct genetic disorders associated with glucose intolerance and, in some cases, clinical diabetes (Table 86-1). Although individually rare, these syndromes demonstrate that mutations at many different loci can produce glucose intolerance. Furthermore, they illustrate the wide variety of pathogenetic mechanisms that can result in glucose intolerance. These mechanisms range from absolute insulin deficiency due to pancreatic degeneration (in such disorders as hereditary relapsing pancreatitis, cystic fibrosis, and polyendocrine deficiency disease) to relative insulinopenia (in the growth hormone deficiency syndromes), to inhibition of insulin secretion (in the hereditary pheochromocytoma syndromes associated with elevated catecholamines), to various deficits in the interaction of insulin and its receptor (in the

**TABLE 86-1 Genetic Syndromes Associated with Glucose Intolerance and Diabetes Mellitus**

Syndromes	Types of DM	Associated Clinical Findings	Pattern of Inheritance	McKusick
<b>Syndromes associated with pancreatic degeneration</b>				
Congenital absence of the pancreas	Type 1 (congenital)	IUGR, poor adipose and muscle, malabsorption, dehydration	AD, ?AR	260370
Immunodysregulation, Polyendocrinopathy, and enteropathy, X-linked (IPEX)	Type 1 (congenital)	IUGR, dehydration, ±fatal secretory diarrhea	XR	304790
Congenital pancreatic hypoplasia	Type 1 (infancy)	IUGR, pancreatic exocrine deficiency	?AR	260370
Permanent neonatal diabetes mellitus with pancreatic and cerebellar agenesis	Type 1 (infancy)	IUGR, cerebellar hypoplasia/agenesis, optic nerve hypoplasia, beaked nose, dysplastic ears, triangular face, decreased subcutaneous fat	AR	609069
Hereditary pancreatitis	IGT, Type 1	Abdominal pain, chronic pancreatitis, portal and splenic vein thrombosis	AD	167800
Cystic fibrosis	IGT, Type 1	Malabsorption, chronic respiratory disease	AR	219700
Polyendocrine deficiency disease (Schmidt syndrome)	Type 1	Autoimmune endocrine disease, hypothyroidism, hypoadrenalism, female predominance, usually onset in middle age	?AR, AD	269200
IgA deficiency, malabsorption and diabetes	Type 1	IgA deficiency, malabsorption	?AD	137100
Hemochromatosis (includes juvenile hemochromatosis (HFE2), HFE3 and HFE4)	Type 2	Hepatic, pancreatic, skin, cardiac, and endocrine complications of iron storage	AR	235200
Thalassemia	IGT→Type 2	Anemia, iron overload	AR	602390
α-1-antitrypsin deficiency	IGT	Emphysema, cirrhosis	AR	604250
Cystinosis, Nephropathic	Type 1	Failure to thrive, Fanconi syndrome and renal failure, photophobia and decreased visual acuity because of corneal crystals, rickets, hepatosplenomegaly, hypopigmentation, primary hypothyroidism	AR	606069
Tropical calcific pancreatitis	Type 1	Juvenile-onset pancreatitis, insulin-dependent but ketosis-resistant diabetes, pancreatic cancer	AR (may require additional mutations in other genes as well)	141900
<b>Disorders causing neonatal diabetes without pancreatic degeneration</b>				
Transient neonatal diabetes	Neonatal→Type 2	Transient neonatal diabetes that resolves at a median age of 3 months, many develop type 2 diabetes later in life, IUGR, macroglossia, abdominal wall defects, brain anomalies, congenital heart disease depending on the gene involved and whether hypomethylation of other genes occurs	AR AD or AR AD Imprinting (hypomethylation) abnormalities of chr. 6q24	107400 219800
Permanent neonatal diabetes	Neonatal	Permanent diabetes beginning in early infancy, IUGR, DEND (developmental delay, epilepsy and neonatal diabetes) associated with KCNJ11 mutations	AR AD AD AD or AR	608189

**TABLE 86-1 Genetic Syndromes Associated with Glucose Intolerance and Diabetes Mellitus—cont'd**

Syndromes	Types of DM	Associated Clinical Findings	Pattern of Inheritance	McKusick#
Neonatal diabetes with congenital hypothyroidism	Neonatal	Congenital hypothyroidism and diabetes	AR	610199
Neonatal diabetes with cerebellar agenesis	Neonatal	Cerebellar agenesis and diabetes, dysmorphic facies	AR	609069
<b>Hereditary endocrine disorders with glucose intolerance</b>				
Isolated growth hormone deficiency	Type 2	Proportionate dwarfism	AD	173100
			AR	262400
Hereditary panhypopituitary dwarfism	Type 2	Proportionate dwarfism hypogonadism ± TSH and ACTH deficiency	AR	262600
			XR	312000

Turner syndrome	IGT→Type 2	Short stature, gonadal dysgenesis, web neck	45, XO	

AD, autosomal dominant; AR, autosomal recessive; Type 1, Type 1 insulin-dependent diabetes mellitus; IGT, impaired glucose tolerance; IUGR, intrauterine growth retardation; JRA, juvenile rheumatoid arthritis; MR, mental retardation; Type 2, Type 2 non-insulin-dependent diabetes mellitus.

nonketotic insulin-resistant states, such as myotonic dystrophy and the lipotrophic diabetes syndromes), to relative insulin resistance (in the hereditary syndromes associated with obesity). Even within these individual categories, further division can be made, either by mechanism or by genetic criteria. For example, the lipotrophic syndromes—characterized by the total or partial absence of adipose tissue, hyperlipidemia, insulin resistance, nonketotic diabetes mellitus, increased basal metabolic rate, and hepatomegaly—can be further subdivided into a recessive, several dominant, and nongenetic forms (10) (MIM#’s 604367, 608594, 608600, 269700, 207780). Even within a more restricted phenotype, such as that of type 1 diabetes, these disorders demonstrate formal linkage heterogeneity. Thus neither the diabetes insipidus optic atrophy (Wolfram) syndrome, nor Friedreich ataxia, both of which clearly cause an insulin-dependent form of diabetes, are linked to the HLA region on chromosome 6 (11–13). In fact, frataxin, the gene for Friedreich ataxia, is located on the long arm of chromosome 9 (14), and the genes (WFS1 and CISD2 [WFS2]) causing Wolfram syndrome are located on the short and long arms of chromosome 4, respectively (15,16).

There are a variety of syndromes that are characterized by marked insulin resistance. The pathophysiology of the resistance of many of these disorders has been defined by studies of the insulin receptor and its interactions, with some disorders characterized by decreased receptor number, others by decreased receptor affinity, and still others by humoral antagonists to the receptor (17,18). A number of distinct molecular defects in the insulin receptor gene have been described in leprechaunism (Donohue syndrome), Rabson Mendenhall syndrome, and type A acanthosis nigricans syndrome (see MIM ID \*147670 for a description of the various mutations; (19, 20)). It is of interest that these affected individuals are often homozygous for a mutant allele or are compound heterozygotes. Relatives who are heterozygous for these defects have been found to have hyperinsulinemia without hyperglycemia (21). Even within what is felt to be one genetic entity, multiple endocrine neoplasia syndrome type 1, an autosomal dominant disorder characterized by pituitary, parathyroid, and pancreatic adenomas, a variety of different hormonal mechanisms can result in insulin antagonism (e.g. eosinophilic adenomas of the pituitary may secrete growth hormone, adenomas of the adrenal gland can secrete cortisol, and non-beta islet cells of the pancreas can produce glucagon) (22). Individually, each of the hormones is an insulin antagonist and their excess can lead to marked glucose intolerance. Thus, each of these many different genetic diseases are capable of resulting in carbohydrate intolerance through a variety of different pathogenetic mechanisms.

More recently, a distinct form of diabetes, presenting in very young infants, has also been found to be genetically heterogeneous (23). In one form of neonatal diabetes, transient diabetes develops at birth or shortly

thereafter but resolves after a few months. Such transient neonatal diabetes can result from mutations in at least three genes (ZFP57, ABCC8, KCNJ11) or from altered imprinting of a region of chromosome 6q24. Depending on the specific gene and mutation, the diabetes can be accompanied by intrauterine growth retardation, macroglossia, abdominal wall defects, congenital heart disease, and/or brain malformations. In addition, mutations in ABCC8, KCNJ11, INS, GCK, GLIS3, and PTF1A can produce permanent forms of neonatal diabetes, with or without additional abnormalities. Identifying the specific genetic mutation becomes critical in these conditions, as this will determine the most appropriate way to treat the diabetes.

These rare syndromes suggest that a similar degree of heterogeneity, both genetic and pathogenetic, may exist in “idiopathic” diabetes mellitus.

### 86.4.2 Heterogeneity Between Type 1 and Type 2 Diabetes

As summarized in Table 86-2, a number of lines of clinical and genetic evidence have led to the eventual separation of type 1 and type 2 diabetes as clearly distinct groups of disorders. Clinical differences that tended to run true in families provided some of the first evidence (24–28). In addition, the extensive MZ twin studies by Pyke and his coworkers in England strongly supported the separation of juvenile insulin-dependent and maturity non-insulin-dependent diabetes (29). Among 200 pairs of MZ (identical) twins, concordance for diabetes was shown to be less than 50% for type 1 diabetes, but close to 100% for type 2 diabetes. This suggested that there are a large group of individuals with type 1 diabetes in whom nongenetic as well as genetic factors may play a role in the development of clinical disease.

Physiological studies further supported the separation of type 1 and 2 diabetes. The absolute insulinopenic response of juvenile-onset diabetics versus the relative hyperinsulinemic response of maturity-onset diabetes parallels the therapeutic observation of the absolute insulin requirement of the juvenile (type 1) diabetic, which contrasts with the ability to manage most adult cases with oral hypoglycemics and/or diet (type 2 diabetes).

Immunologic studies pinpointed the importance of immune mechanisms in the etiology of type 1 but not type 2 diabetes. Direct evidence for an autoimmune role in the pathogenesis of type 1 diabetes came from the discovery of organ-specific cell-mediated immunity to pancreatic islets, and then the successful demonstration of antibodies to the islet cells of the pancreas (30). While these antibodies were first detected only in insulin-dependent diabetics with coexistent autoimmune endocrine disease, it soon became apparent that they were common (60–80%) in most newly diagnosed juvenile diabetics. Studies on islet cell antibodies (ICA) supported the differentiation of insulin-dependent from

**TABLE 86-2 Separation of Type 1 from Type 2 Diabetes**

Other Nomenclature	Type 1 IDDM (Juvenile-Onset Type)	Type 2 NIDDM (Maturity-Onset Type)
(1) Clinical	Thin Ketosis prone Insulin required for survival Onset predominantly in childhood and early adulthood	Obese Ketosis resistant Often treatable by diet or drugs Onset predominantly after 40
(2) Family studies	Increased prevalence of juvenile or type 1	Increased prevalence of maturity or type 2
(3) Twin studies	<50% concordance in monozygotic twins	Close to 100% concordance in monozygotic twins
(4) Insulin response to a glucose load	Flat	Variable
(5) Associated with other autoimmune	Yes	No endocrine diseases and antibodies
(6) Islet cell antibodies and pancreatic	Yes	No cell-mediated immunity
(7) HLA associations and linkage	Yes	No

non-insulin-dependent diabetes, as autoantibodies were present in 30–40% of the former group (even after onset) as opposed to 5–8% of the latter. Many (probably the majority) of the non-insulin-dependent, yet antibody positive, patients appear to become insulin dependent with time. They have flat insulin responses to a glucose load, and they also have the HLA-associated DR3 and DR4 antigens (31). This has suggested that etiologically, these cases belong to the insulin-dependent category (i.e. they are just in a transitional state on the way to eventual insulin dependence and share the same underlying pathogenic mechanisms as type 1 diabetes). Thus immunologic studies have served both to separate disorders (juvenile versus adult) and combine others (insulin dependent and non-insulin dependent, yet antibody positive).

Finally, the clear and consistent findings of HLA associations with juvenile insulin-dependent, but not maturity-onset non-insulin-dependent diabetes, became a major argument for etiologic differences between these two disorders; approximately 95% of type 1 diabetes patients have DR3 or DR4 or both (reviewed in (4,32)).

Based to a large extent on the evidence reviewed previously, the American Diabetes Association's current classification divides diabetes mellitus into four major subcategories: type 1 diabetes (insulin-dependent diabetes), type 2 diabetes (non-insulin-dependent diabetes), gestational diabetes, and other specific types of diabetes (33). The major defining characteristics of each of these categories are summarized in Table 86-3.

There is, however, some evidence that families of either type 1 or type 2 diabetes have more of the other type of diabetes than do families in the general population (34). Part of this overlap may be attributed to the insulin-independent phase of the insulin-dependent type (the frequency of which is still being defined), but it may also be the result of even further etiologic heterogeneity (see later discussion). In addition, the age of onset and other clinical differences can be important. For example, a distinct form of non-insulin-dependent diabetes that has been termed "maturity-onset diabetes of the young" (MODY) has been described (35) (discussed later).

The delineation of this entity clearly demonstrated that age of onset is a useful clinical criterion for classification purposes. Similarly, there is evidence that the age of onset may still be helpful as an additional classification criterion in type 1 diabetes, in that those individuals with both DR3 and DR4 alleles have the youngest age of onset. It has also been recognized that adults may develop type 1 diabetes, often with a less dramatic presentation than in children; this has been termed latent autoimmune diabetes of adults (LADA).

### 86.4.3 Type 1 (Insulin-dependent) Diabetes Mellitus

Type 1 diabetes mellitus is characterized by low levels or absence of endogenous insulin production (see Table 86-3). This is secondary to destruction of the insulin-producing beta cells of the pancreas and is the single characteristic that most decisively separates type 1 and type 2 diabetes. It is estimated that 5–10% of all US patients with diabetes have type 1 diabetes, and that the US incidence in children aged 0–14 years is in the range of 12 per 20/100,000 (36). The incidence appears to vary dramatically worldwide, from an estimated low of 1 per 100,000 children in parts of Asia and South America to greater than 40 per 100,000 in some regions in Scandinavia (36–39). In most regions of the world, the incidence appears to be increasing (38,40–43). The increasing incidence suggests that some environmental risk factor(s) for type 1 diabetes are becoming more prevalent, but the nature of these environmental risks is still under investigation.

### 86.4.4 Natural History and Pathophysiology of Type 1 Diabetes

Patients with a new diagnosis of type 1 diabetes typically present acutely ill, with severe dehydration, ketoacidosis, and marked hyperglycemia. The history is generally that the individual was well until perhaps a week or two before presentation, when increased thirst and urination were noted. Occasionally an account

**TABLE 86-3 Etiologic Classification of Diabetes Mellitus**

Class Name	Former Terminology	Characteristics
Type 1 diabetes <sup>a</sup>	Insulin-dependent diabetes (IDDM)	β-cell destruction, usually leading to absolute insulin deficiency
Immune mediated	Juvenile diabetes	Dependent on injected insulin to prevent ketosis and sustain life
Idiopathic	Juvenile-onset diabetes (JOD)	Onset predominantly in youth but can occur at any age Associated with HLA DR3 and DR4 Islet cell antibodies are frequently present before and at diagnosis
	Ketosis-prone diabetes	
	Brittle diabetes	
Type 2 diabetes <sup>a</sup>	Non–insulin-dependent diabetes (NIDDM)	May range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance
	Adult-onset diabetes	Insulin levels may be normal, elevated, or depressed
	Maturity-onset diabetes (MOD)	
	Ketosis-resistant diabetes	
	Stable diabetes	Not insulin-dependent or ketosis-prone under normal circumstances, but may use insulin for treatment of hyperglycemia or during stress conditions Onset predominantly after age 40, but can occur at any age Approximately 60% of patients are obese Hyperinsulinemia and insulin resistance characterize some patients
Gestational diabetes (GDM)	Gestational diabetes	Glucose intolerance that has its onset during pregnancy; (GDM) virtually all patients return to normal glucose tolerance following parturition Conveys increased risk for progression to diabetes
Other specific types includes: Genetic defects of β-cell function	Secondary diabetes	In addition to the presence of the specific condition, hyperglycemia at a level diagnostic of diabetes is also present
Genetic defects in insulin action		
Diseases of the exocrine pancreas		
Endocrinopathies		
Drug- or chemical-induced infections		
Uncommon forms of immune- mediated diabetes		
Other genetic syndromes sometimes associated with diabetes		

<sup>a</sup>Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient. Data from National Diabetes Data Group, 1979 (485), Expert Committee on Classification, American Diabetes Association, 2003 (33).

is given of a viral upper respiratory tract infection or other mild infectious illness shortly before the increased thirst and urination began. As a result, for many years, type 1 diabetes was thought to be an acute onset disorder. However, with the appreciation of the autoimmune nature of the beta cell destruction, this assumption began to be questioned.

Several studies followed nondiabetic identical cotwins and triplets of type 1 diabetic probands with serial testing for the presence of circulating autoantibodies (44,45) and, not surprisingly, many of these twins and triplets ultimately developed type 1 diabetes. What was

not anticipated, however, was that anti-ICA were often detectable months to many years before the time when these cotwins became overtly diabetic. These studies demonstrate that the development of type 1 diabetes actually occurs gradually. A variety of abnormalities in immune function and insulin release precede the “abrupt” development of the diabetic syndrome in patients genetically predisposed to type 1 diabetes (46). Eisenbarth (47) proposed dividing the development of type 1 diabetes into six stages: (1) genetic susceptibility; (2) triggering events; (3) active autoimmunity; (4) gradual loss of glucose-stimulated insulin secretion;

(5) appearance of overt diabetes, with some residual insulin secretion; and (6) complete beta cell destruction. The autoimmune destruction of pancreatic beta cells progresses slowly over time, and it is not until the majority of these cells have been destroyed that clinically apparent diabetes occurs. At the onset of type 1 diabetes, as little as 10% of the beta cells remain and, within several years, essentially all beta cells are destroyed (46). Maclaren (48) also pointed out that the pace of these events may well relate to the age of onset and the underlying genetic heterogeneity.

Nonobese diabetes (NOD) mice and biobreeding (BB) rats are excellent models of the autoimmune form of type 1 diabetes (see recent reviews in (49–51)). Data from these animal models indicate that T lymphocytes are important in the pathogenesis of islet T-cell destruction, as activated T lymphocytes from acute-diabetic BB rats can transfer diabetes to other animals (52). Similar evidence for the importance of T lymphocytes in human diabetes comes from the studies of pancreatic transplantation between identical twins (53,54). When pancreata were transplanted from nondiabetic twins to their diabetic MZ cotwins without immunosuppression, islet cell destruction with massive T-cell infiltration and relapse of the diabetes occurred within weeks. Thus, the basic defect in type 1 diabetes appears to be extrinsic to the pancreas and related to the activation of T lymphocytes, which then mediates the destruction of the islets (46).

The mechanisms resulting in the autoimmune destruction of the islets are complex. Although both T cells and the cytokines they excrete are directly involved in the destruction, it has become increasingly clear that it is not just autoreactive T cells that are important. Macrophages, natural killer cells, dendritic cells and altered Treg cell function have also been implicated (55). In light of the complex processes involved, it has been difficult to identify what the initiating abnormality is that triggers the autoimmune process. Given the many immune-related genes that are now implicated in type 1 diabetes, it is likely that the combination of a number of alterations in immune function is necessary to initiate beta cell destruction.

Because it is estimated that at diagnosis of type 1 diabetes about 10% of beta cells are still alive and capable of producing insulin, some patients go through a transient “honeymoon” phase in the early months after diagnosis, during which their requirement for exogenous insulin may decrease or even disappear. These remaining beta cells are lost within the first months to years following diagnosis, however, and all patients ultimately will require lifelong treatment with insulin.

With the recognition that there were functional beta cells still present at the time of diagnosis, treatment with immunosuppressants was attempted to see if type 1 diabetes could be reversed. Although it was possible to produce a remission in some patients who were

treated with cyclosporine within the first few months after diagnosis, the effect was short lived in most cases and overt diabetes returned as soon as cyclosporine was discontinued (56,57). More recent attempts to produce remission have utilized more narrowly targeted agents, such as humanized anti-CD3 or anti-CD20 monoclonal antibodies. While none of the subjects treated with these agents went into remission, there was evidence of preservation of C-peptide levels and in some cases a reduced insulin requirement was observed (58–60). The observation that these effects may persist for several years after short-term treatment is encouraging (60,61). At present, while research continues, there is no proof that it will be possible to cure diabetes once beta cell destruction has progressed to the point of overt diabetes. Therefore, attention has also been focused on attempts to intervene in high-risk individuals who have not yet progressed to clinical diabetes (see later discussion).

#### 86.4.5 Penetrance of Type 1 Diabetes

When the mode of inheritance is unknown, the only estimate we have for penetrance comes from identical twin concordance data. The largest twin data set (the British diabetic twin study) reported concordance for type 1 diabetes of some 50% of cases (29,62). However, it is clear that this sample is an unrepresentative one, with only a fraction of the twins in the British Isles identified, and thus there is a presumed bias toward concordant pairs (63). Studies of less-biased, but much smaller, samples reported concordances of approximately 20% (64). Finally, in 1988, a prospective study of twins from the British group yielded a concordance estimate of about 36%, an estimate similar to that in a recent (2009) study from Sweden (65,66). While the best estimate is that perhaps only one-third of all persons with the genes for type 1 diabetes actually develop clinical disease, one recent study has suggested that the concordance may be higher if twins are followed up long term (67).

Whichever estimate is used, however, it is clear that MZ twin concordance is substantially less than 100%. This reduced penetrance indicates that what is inherited in type 1 diabetes is disease susceptibility; other factors, presumably environmental, are required to convert genetic susceptibility into clinical disease. This view is supported both by the observation of the time of onset of type 1 diabetes clusters in families and twin pairs (68,69) and the epidemiological, experimental, animal, and clinical evidence for viral infections as a supervening factor in at least some cases (70–72) (see later discussion). However, environmental influence is not necessarily the only explanation, as the somatic recombination that occurs within the immune system is also a potential explanation for the reduced penetrance (see later discussion).

### 86.4.6 The HLA Region and Type 1 Diabetes

With the discovery of HLA antigen associations with type 1 diabetes, the genetic region that provides the major (but by no means only) genetic susceptibility to type 1 diabetes was located. The earliest studies implicating the HLA region in type 1 diabetes susceptibility demonstrated an increased frequency of the class I antigens B8 and B15 in white type 1 diabetes subjects (73–75). Subsequently, a large number of studies found an increased frequency of the class II HLA antigens DR3 and DR4 among white type 1 diabetes patients (76,77). Because of the linkage disequilibrium within the HLA region, the associations of B8 and B15 were thought to result from these alleles occurring with a high degree of frequency on DR3-containing (in the case of B8) and DR4-containing (in the case of B15) haplotypes. The type 1 diabetes association is unusual among HLA disease associations, because it involves two antigens, HLA-DR3 and DR4. In addition, the relative risk for type 1 diabetes in individuals who carry both DR3 and DR4 (compound heterozygotes) is greater than those homozygous for either DR3 or DR4 (76–78). This finding of the increased risk of the DR3/DR4 heterozygote was the first suggestion that more than one gene may predispose to type 1 diabetes.

Approximately 95% of all type 1 diabetes (in white populations) have HLA-DR3, DR4, or both, compared with about 50% of individuals in the nondiabetic population (32). There are also more subtle relative increases in HLA-DR1 (especially among those who have only one copy of DR3 or DR4); conversely, DR2 and DR5 are decreased in individuals with type 1 diabetes (79,80). HLA-DR3 and DR4 (as defined serologically) are not pathognomonic of type 1 diabetes; nearly half the US population has either DR3 or DR4 (only 1–3% have both), yet only a small percentage (about 0.5%) of these individuals will develop type 1 diabetes. However, if one's sibling has type 1 diabetes, the chance of a DR3 or DR4 individual developing type 1 diabetes rises sharply (12–24%). These observations suggested that DR3 and DR4 as defined serologically could not adequately explain the risk for type 1 diabetes present in the HLA region. Either the serologic DR typing was not sensitive enough to detect the type 1 diabetes-specific forms of DR3 and DR4 or other genes were responsible for at least some of the type 1 diabetes susceptibility associated with the HLA region.

With the advent of molecular HLA typing, it became clear that both these possible explanations are indeed important in understanding the role of the HLA region in type 1 diabetes susceptibility. Initially, when the complexity of the HLA class II region was uncovered, attention focused on the hypothesis that another locus in tight linkage disequilibrium with DR was actually responsible for type 1 diabetes susceptibility. Studies demonstrated that the HLA class II region consists of at least three

genetic loci: DR, DQ, and DP, each of which codes for a slightly different glycoprotein consisting of two peptide chains, alpha and beta. Because of this variability, there are differences at the DNA level between diabetics and nondiabetics, even when they share the same serologic DR type.

Given the extensive linkage disequilibrium, identifying which class II locus was primarily responsible for type 1 diabetes susceptibility was challenging. Studies in white populations initially implied that the primary locus for type 1 diabetes susceptibility was the DQ beta gene, with the DQB1\*0302 allele being highest risk. However, subsequent studies in other ethnic groups led to the realization that other genes within the class II region clearly are of importance as well. Thus, for example, in Mexican American type 1 diabetes patients, DRB1\*0402-DQB1\*0302 and DRB1\*0405-DQB1\*0302 (European white haplotypes) are strongly associated with risk, whereas DRB1\*0408-DQB1\*0302 and DRB1\*0411-DQB1\*0302 (Native American haplotypes) are actually protective against type 1 diabetes, even though they all contain the DQB1\*0302 allele (81). In most, but not all populations that have been studied, the HLA haplotypes that are commonly associated with risk for type 1 diabetes are DRB1\*0301-DQA1\*0102-DQB1\*0201 and DRB1\*0401-DQA1\*0301-DQB1\*0302, whereas other haplotypes such as DRB1\*1501-DQA1\*0102-DQB1\*0602 are strongly protective against type 1 diabetes (82,83). Such data suggest that at a minimum, the DRB1, DQA1, and DQB1 loci are implicated in diabetes susceptibility. Additionally, the DPB1 locus has also been shown to play a role in type 1 diabetes susceptibility in both white and Mexican American populations (84,85). It thus now appears that many of the class II loci are involved in type 1 diabetes susceptibility, with associations reported with the DQ beta region (DQB1\*0302), DQ alpha region (DQA1\*0301) and the DP beta region (DPB1\*0301), as well as with DR itself (84,86,87).

The HLA region is even more complex, however, extending across approximately 7.6Mb and containing more than 250 genes (88). Because of the extensive linkage disequilibrium across the HLA region, it has proven to be very difficult to determine the loci that actually contribute to type 1 diabetes risk versus those loci that demonstrate associations only as a result of linkage disequilibrium. It is now clear that the HLA class II region is not the only portion of the HLA region conferring risk to type 1 diabetes. Data have been reported suggesting that genes in many other HLA regions may also be involved in disease susceptibility (86,89–96). There is quite strong evidence implicating the HLA-A and B class I genes (87,97). Most recently, a conditional meta-analysis was performed using data from the Wellcome Trust Case-Control Consortium and International Type 1 Diabetes Consortium and it implicated the genes TCF19, POU5F1, CCHCR1, and PSORS1C1 within the class I region (98).

While it is still unclear which of these putative associations will ultimately be confirmed, the observed increased risk for type 1 diabetes in DR3/4 heterozygotes compared with either DR3/3 or DR4/4 homozygotes means that the susceptibility to type 1 diabetes associated with DR3 and DR4 are different. This is reinforced by the observation that familial aggregation of type 1 diabetes suggests that DR3 susceptibility acts in a recessive manner, with most DR3-carrying type 1 diabetes patients also having a second high-risk HLA haplotype (containing either DR3 or DR4). DR4-related type 1 diabetes susceptibility, on the other hand, appears to act in a dominant manner, as demonstrated by the observation of many DR4-carrying type 1 diabetes patients who do not carry a second high-risk haplotype (99).

There is also evidence for phenotypic heterogeneity between type 1 diabetes associated with HLA-DR3 and that associated with HLA-DR4 (Table 86-4) (reviewed in (4)). The DR3 form of the disease is characterized by a greater persistence of pancreatic ICA and antipancreatic cell-mediated immunity, but a relative lack of antibody response to exogenous insulin. This form apparently has onset throughout life and probably accounts for a significant fraction of older-onset type 1 diabetes. In the older age groups, this form of type 1 diabetes may present as latent autoimmune diabetes (LADA) and may be treated without insulin for a significant period, but the presence of ICA presages eventual insulin dependence (100). Type 1 diabetes associated with DR4 is not as strongly associated with autoimmune disease or ICA, but this form is accompanied by an increased antibody response to exogenous insulin (101,102). The relation between HLA-DR4 and insulin immunogenicity also can be seen before the initiation of exogenous insulin therapy, with the occurrence of insulin antibodies before disease onset (103–105). DR4-associated type 1 diabetes also appears to have an earlier age of onset, exhibits seasonality, and may be related to viral infections.

With multiple genes participating, it is clear that the mechanisms by which the HLA region produces susceptibility must be complex. Based on our current understanding of the functioning of the various HLA genes, the alleles associated with increased risk of diabetes likely alter the way that the class I and class II receptors bind peptide antigens and interact with antigen-presenting cells (APCs), CD4<sup>+</sup> T-cells and CD8<sup>+</sup> T cells (106). However, a more complete understanding of these mechanisms must await further clarification of both the number and identity of the HLA-linked genes that account for type 1 diabetes risk.

### 86.4.7 Non-HLA Region Genes and Type 1 Diabetes

Estimates of the proportion of genetic susceptibility to type 1 diabetes for which the HLA region accounts vary, but even the highest estimates are in the range of 60–70%, clearly indicating that other, non-HLA loci must also exist that play a role in type 1 diabetes (99,107,108). Over the past several decades, numerous other regions have been implicated in type 1 diabetes susceptibility, but until the advent of the GWAS era, the data in support of most loci remained fairly tentative.

**86.4.7.1 Candidate Genes and Type 1 Diabetes.** Before GWAS, the best substantiated locus was IDDM2, near the insulin gene on the short arm of chromosome 11. This region was first implicated in the early 1980s, when a polymorphic region 5' to the insulin gene (INS) was discovered (109). The polymorphism results from the presence of a variable number tandem repeat (VNTR) region near the 5' regulatory region of INS. A number of population studies reported an association between type 1 diabetes and class I alleles, which have smaller numbers of tandem repeats in this region as compared to the class III alleles (110,111). Although it is now appreciated that classical linkage methods are

**TABLE 86-4 Heterogeneity within Type 1 Diabetes**

Evidence	DR3	DR4	Combined Form (DR3/DR4)
Linkage disequilibrium	A1, B8	B15, DQβ1*0302	Penetrance in MZ twins
Insulin antibodies	Nonresponder (low antibody titers)	High responder (high antibody titers)	Occurrence in familial cases
Islet cell antibodies	Persistent	Transient	
Insulin autoantibodies	Less frequent	Increased frequency	Highest titers
Antipancreatic cell-mediated immunity	Increased	Not increased	
Thyroid autoimmunity in	Yes	Less frequent Type 1 DM	
Associated with other autoimmune	Yes	No endocrine diseases	
IgA deficiency in	Increased	Not increased Type 1 DM	
Age of onset	Any age	Younger age	Youngest
Ketoacidosis at	Lesser frequency	Greater frequency clinical onset	
Levels of C-peptide	Preserved longer	Absent after shorter duration	Lowest

rarely informative when analyzing loci contributing a comparatively small amount to disease susceptibility, when these association studies were followed by family studies that failed to demonstrate linkage, there was some controversy as to whether the association was real or not. With the advent of family-based association methodologies, a role for IDDM2 was better substantiated and this locus became the second (after HLA) well accepted in type 1 diabetes susceptibility locus (110–112).

For many years, however, questions remained about how this region results in diabetes susceptibility, until it was shown that it affects expression of insulin mRNA in the fetal thymus and thus influences the development of tolerance to antigenic determinants of insulin (113,114). Class I alleles, which contain smaller numbers of repeats and are associated with increased risk for diabetes, have been observed to result in lower insulin gene mRNA expression in the thymus. The other common allele size, known as Class III alleles, has greater numbers of repeats within the VNTR and has been associated with decreased diabetes risk and increased thymic mRNA levels. Recently Cai et al. (115) showed that the mechanism for this altered expression involves the autoimmune regulator (AIRE) protein, which interacts with the INS VNTR to regulate insulin expression. The correlation between VNTR length and thymic expression is not absolute, however. Vafiadis and coworkers (116) observed that in a minority of subjects, silencing of the Class III allele occurs, resulting in thymic expression from the other insulin allele. Such silenced Class III alleles predispose to type 1 diabetes, presumably because they lead to overall reduced mRNA levels. At the level of the VNTR, the mechanism responsible for silencing has not yet been identified but is hypothesized to result from altered imprinting.

CTLA4, cytotoxic T-lymphocyte-associated protein 4, is a member of the immunoglobulin superfamily, and was tested as a candidate gene within the IDDM12 linkage region on chromosome 2q33, which was homologous to the *Idd5* locus in the mouse. Association with type 1 diabetes was demonstrated in several ethnic groups, as well as associations with several other autoimmune disorders, especially thyroid disease (117–126). CTLA4 is a negative immunoregulatory molecule involved in T-cell activation and expansion that appears to be important in normal Treg function (127,128).

PTPN22 encodes the lymphoid-specific protein tyrosine phosphatase (LYP), which is another inhibitor of T-cell activation (83,129,130). The 1858 T allele, which replaces arginine with a tryptophan residue at codon 620, was originally reported to be associated with type 1 diabetes by Bottini et al. (131). Like CTLA4, it has also been implicated in other autoimmune diseases, including rheumatoid arthritis, autoimmune thyroid disease, lupus, celiac disease, and autoimmune vasculitis (122,132–135). The associated allele results in a gain of

function (136), suggesting that inhibitors of LYP could be of therapeutic benefit.

IL2RA, interleukin 2 receptor A gene (also known as CD25), was first reported to be associated with type 1 diabetes by Vella et al. (137) and subsequently replicated (138–140). Like CTLA4 and PTPN22, IL2RA is associated with risk for other autoimmune diseases including Graves' disease, multiple sclerosis, and juvenile idiopathic arthritis (141–143). The mechanism by which IL2RA results in risk for autoimmune disease is still under study, but the allele associated with protection against type 1 diabetes results in higher CD25 levels on CD4+ memory cells and such cells are likely more responsive to IL-2 and to TCR-mediated activation (144).

#### 86.4.8 Identifying Type 1 Diabetes Genes by Genome-Wide Linkage Scans

With the application of systematic linkage mapping to type 1 diabetes, a variety of other candidate gene regions were mapped. Some of the linkage regions corresponded to previously known loci, including HLA and INS. Studies of candidate genes within other regions, including CTLA4 (located within the IDDM 12 region on chromosome 2q and SUMO4 in the IDDM5 region on chromosome 6q), appear to explain the observed linkage peaks (118,121,145–150). Data suggest that SUMO4 contributes to type 1 diabetes susceptibility in Asians, but it is less clear whether this gene is important in Caucasian populations (140,149–151). Data for other regions have been equivocal and many may ultimately turn out to have been false positives.

#### 86.4.9 Type 1 Diabetes Genes Identified by Genome-Wide Association Studies

GWAS have resulted in the identification of a substantial number of genes for type 1 diabetes (Table 86-5). This has been facilitated by cooperation between multiple centers, both in the acquisition of large numbers of cases and controls and in data sharing to confirm association signals. The first genome-wide association study for type 1 diabetes was published in 2006 reporting an association with the innate immunity viral RNA receptor gene region, IFIH1 (152). This was followed rapidly by a number of other GWAS (153–156) that increased the number of loci demonstrating association. Additional loci have been identified by GWAS meta-analyses using very large combined study populations (one with more than 3500 cases and 4500 controls (157) and a second with more than 7500 cases and 9000 controls (158)). Many of the GWAS and meta-analysis findings have also been confirmed in independent samples, and as of early 2011, there are more than 50 loci with quite convincing evidence for association with type 1 diabetes (Table 86-5; see also <http://www.t1dbase.org> (159)).

Adapted from <http://t1dbase.org/> accessed 3/20/2011.

GWAS identify single nucleotide polymorphisms (SNPs) that demonstrate association with a disorder or trait of interest. Occasionally, the associated SNP results in a functional change and is directly responsible for the observed association. More commonly, however, it is unlikely that the associated SNP is actually causing disease risk. In such situations, the SNP association directs research to a specific chromosomal segment, but identifying which genes within the associated regions and which variants within specific genes are responsible for type 1 diabetes susceptibility continues to be a challenge. Many of the GWAS loci contain genes that are involved in immune function, which are good candidates. In addition, a number of the same regions have been identified in GWAS performed for other autoimmune diseases, including rheumatoid arthritis, systemic lupus erythematosus, multiple sclerosis, celiac disease, Graves' disease, Crohn's disease, and vitiligo. Based on such observations, it is likely that some loci are associated with a generalized risk for autoimmunity, whereas other loci may provide the specificity that determines exactly which autoimmune disease will present clinically. Understanding the ways in which the various loci interact to produce type 1 diabetes will only be possible after the actual susceptibility genes and functional variants have been definitely identified.

What also remains to be clarified is how many genes are involved in type 1 diabetes susceptibility. As is true with all complex genetic disorders, the genes and loci known from candidate gene studies and GWAS still do not account for all the observed heritability of the disease. One possible explanation for this "missing heritability" is that rare variants that are not detectable using current analytic methods and sample sizes may contribute to disease. On the assumption that such rare variants will only be identifiable from sequencing, exome and whole-genome sequencing projects are now underway. While it is expected that these approaches will increase the proportion of heritability that can be explained, other factors, including gene–gene interactions, epigenetic factors, copy number variations, noncoding RNAs that affect gene expression, and gene–environment interactions, may also be implicated.

#### 86.4.10 The Role of Environmental Factors in Type 1 Diabetes

The possibility that there are important environmental components to the etiology of type 1 diabetes is raised by the MZ twin data, which show a type 1 diabetes concordance of approximately 20–40%. As discussed previously, the lack of 100% concordance in MZ twins does not absolutely require the involvement of environmental factors; immunologic gene rearrangements could also provide an explanation for such a reduced penetrance (160–162). Yet the possibility of environmental factors having a significant role must be thoroughly investigated,

especially as regards the implications for preventive strategies. Environmental effects on diabetes development have been postulated going back to the 1920s, based on the observation of seasonal variations in the diagnosis of diabetes in children and young adults (163). As the pathogenetic processes that lead to type 1 diabetes appear to be complex and may take years from initiation to completion, environmental agents could function as initiating factors (i.e. factors that begin the etiologic processes that eventually terminate in type 1 diabetes), or, alternatively they could act mainly as precipitating factors (i.e. factors that convert preclinical diabetes into clinical disease). In either role (or both), what is clear is that environmental factors must act on genetically susceptible individuals for type 1 diabetes to occur. Several classes of environmental agents have been implicated in the etiology of type 1 diabetes.

**86.4.10.1 Infectious Agents.** A viral etiology for diabetes has been suggested for many years, with case reports of diabetes following an episode of an infectious disease dating back to the 1800s (164,165). The current evidence for a role of viral agents comes from several sources, including case reports, epidemiological studies, clinical studies, and evidence from animal and human models.

Anecdotally, a "viral-like illness" is known to precede the onset of many cases of type 1 diabetes (166). Several lines of epidemiological evidence are also consistent with an infectious etiology. For example, it has been noted that trends in age at onset of diabetes are consistent with a viral etiology (69). The total number of infections during the preceding year has been shown to correlate with type 1 diabetes risk (167).

Another suggestion that environmental agents play a role in the etiology of type 1 diabetes comes from studies of time of clinical disease onset in pairs of siblings with type 1 diabetes. At least one study suggested that sibling pairs are more likely to have their onset of diabetes within a year of one another than would be expected by chance (69). Similarly, the period of discordance for type 1 diabetes in MZ twins where both ultimately develop type 1 diabetes has been reported to be less than 3 years in 60% (168).

There is also limited evidence for an infectious agent's role (e.g. mumps, coxsackie) from seroepidemiological studies (i.e. studies that compare viral and bacterial antibody titers in type 1 diabetics and nondiabetic controls) (71,72,166). While some studies have suggested an association, there have also been many negative studies. Green and colleagues (169) performed a systematic review of all case-control studies examining Coxsackie viruses and found a range of odds ratios from 0.2 to 22.3 for type 1 diabetes mellitus in serology-positive vs. serology-negative subjects; 7 of 13 studies had point estimates significantly greater than 1.0 ( $P < 0.05$ ). Additionally, studies have utilized molecular techniques to determine the prevalence of viral DNA. For example,

Nairn and colleagues (170) reported detection of enterovirus RNA in 27% of children with new-onset type 1 diabetes as compared to only 4.9% of controls and a recent meta-analysis of multiple studies has provided further support (171).

The effect of childhood immunization on type 1 diabetes susceptibility has also been controversial. Although a study of the incidence of type 1 diabetes in relationship to the introduction of the measles-mumps-rubella vaccination and the subsequent disappearance of mumps in Finland suggested that elimination of natural mumps infection has decreased the incidence of type 1 diabetes (172) and measles vaccination by itself correlated with a lower risk of type 1 diabetes (167), the observation that an increasing incidence of type 1 diabetes has paralleled the expansion of childhood immunization has resulted in postulation that one or more of these vaccines may increase diabetes risk. While a number of large-scale studies appear to have disproven this hypothesis (173–175), it remains a concern for many, particularly among parents' groups.

If indeed viral infections do play a role in the development of overt diabetes, the question that must be asked is what mechanisms are involved. The insulinitis that has been noted in early type 1 diabetes could be consistent with viral infection of the pancreas, and autopsy studies have clearly documented pancreatic beta cell damage in children dying from overwhelming viral infections (176). Coxsackie B-specific antigens have specifically been found in the islets of Langerhans, and the coxsackie B4 virus itself has been isolated from the pancreas of a child dying of acute-onset type 1 diabetes (177) as well as from pancreata removed from diabetic patients undergoing organ transplantation (178). Several types of viruses are known to be capable of infecting human pancreatic beta cells in vitro, and data suggest that coxsackie virus B groups, rubella virus, and possibly cytomegalovirus are capable of producing pathologic beta cell changes in vivo.

Molecular mimicry has also been postulated to be a mechanism by which viral infection can impact the development of type 1 diabetes (179). There are regions of sequence homology between glutamic acid decarboxylase (GAD) and the p2C protein of coxsackie B virus, and between regions of both GAD and tyrosine phosphatase IA-2 and the VP7 protein of rotavirus (180,181). IA-2 also demonstrates significant sequence homologies with a variety of other viral genomes, including dengue, CMV, measles, and hepatitis C (182). Such observations raise the possibility that viral infection can trigger an anti-beta cell autoimmune response by such molecular mimicry. This possibility is further supported by the observation that the homologous peptides from VP7 and IA-2 both bind to HLA-DR4 (\*0401), whereas peptides from p2C and GAD both bind to DR3 (182,183). Antibodies to GAD species and to the p2C protein have also been shown to cross-react

in some, but not all, studies. Some authors have argued that molecular mimicry with viral proteins may actually play more of a role in the activation of preexisting auto-reactive T cells than in de novo stimulation of an autoimmune response (184). In this case, a viral infection could act to precipitate the development of diabetes by acutely exacerbating a previously existing low-grade autoimmune process.

The best human models of infectious agents in type 1 diabetes come from studies of individuals with the congenital rubella syndrome and from serial studies of children with viral infections who subsequently develop type 1 diabetes. The incidence of type 1 diabetes and other autoimmune diseases among children and young adults with the congenital rubella syndrome is markedly increased over that in the general population and may be as high as 15–40%. Those cases of congenital rubella with type 1 diabetes have an increased frequency of HLA-DR3 and DR4 and a decreased frequency of HLA-DR2, much as in non-rubella type 1 diabetes cases (185). A significant proportion of patients with congenital rubella syndrome have T-cell subset abnormalities, and a variety of autoimmune antibodies, including anti-thyroid microsomal, anti-thyroglobulin, and anti-islet cell and islet-cell surface antibodies, suggesting an autoimmune etiology for their type 1 diabetes (185,186). Rubella virus has been isolated from the pancreas of several cases with congenital rubella syndrome (187), and at least one case is known of insulinitis and beta cell destruction in an infant with congenital rubella infection who died of acute diabetes (188). This evidence suggests that rubella can indeed infect and damage the beta cell, and that the diabetes seen in congenital rubella syndrome could be due either to initiation of an immune process by the rubella virus, or directly to persistent pancreatic rubella infection.

**86.4.10.2 Dietary Agents and Molecular Mimicry.** A continuing area of interest regarding environmental triggers for type 1 diabetes has been dietary exposure. In the 1990s several studies reported an association of the introduction of cow's milk and cessation of breast feeding with type 1 diabetes risk (189–193). Elevated antibodies to several cow's milk proteins have also been found in children with type 1 diabetes (193,194). When it was reported that one epitope of bovine serum albumin, a 17-amino-acid residue peptide (ABBOS) cross-reacts with p69, a beta cell surface protein, the hypothesis was raised that early introduction of cow's milk into the infant diet could result in initiation of autoimmune injury to the beta cell via this molecular mimicry (195,196). In addition to bovine albumin, the hypothesis has been put forward that bovine insulin in cow's milk could trigger development of anti-insulin antibodies (197). However, several subsequent large studies of infant nutrition have not supported the association of autoimmunity to cow's milk and type 1 diabetes risk and the likelihood that cow's milk has a significant effect on risk now appears

small (198–200). Despite these studies, the possible role for dietary exposure in diabetes risk remains a topic of study. Dietary exposures may, for example, influence the development of type 1 diabetes in individuals who are genetically at high risk (201,202). To date, however, the data appear to argue more strongly for infectious triggers than for dietary ones.

### 86.4.11 Genetic Counseling in Type 1 Diabetes

Because the mode of inheritance in type 1 diabetes is not straightforward, most genetic counseling for type 1 diabetes is based on empirical risk estimates, which have been developed from both population-based and family-based epidemiological studies (Table 86-6). These recurrence risks are frequently reassuring to families, as the risks are often less than the family has feared, particularly for siblings of the type 1 diabetes patient. The empirical risk of recurrence for type 1 diabetes is dependent on the relationship of the individual in question to the affected family member. For siblings the empirical risk is approximately 5–10%. If the father is affected, the risk to his offspring is 4–6%, compared with 2–3% if the mother is affected (203,204). For further refinement of sibling risks, HLA testing and autoantibodies can be used to determine haplotype sharing with the diabetic sib (205). If two HLA haplotypes are shared, the risk increases to 16–17%, and is 20–25% if the haplotypes contain both DR3 and DR4. Siblings who share one haplotype have a risk in the range of 5–7%, whereas the risk is approximately 1–2% if no haplotypes are shared (4). It is important to realize that

the sibling of an individual with type 1 diabetes still has a risk for type 1 diabetes that is increased above that of the general population, even when the sib shares no HLA haplotypes in common with the diabetic in the family.

There is some question regarding the benefit of performing genotyping or autoantibody testing for the siblings of an individual with type 1 diabetes when at present it will not lead to any alteration in management. While testing may be performed as part of research studies examining possible prevention strategies, at present there are no proven therapies for individuals who are found to be at high risk. Particular attention must be paid to the potential negative effects of stigmatization and the risks of the child being treated as though he is ill. The concept that HLA testing at best identifies someone more susceptible to developing type 1 diabetes but in no way guarantees that she will become diabetic must be stressed in discussions with the family. The potential for other negative effects, such as possibly being ruled ineligible for health, life, and/or disability insurance because of the presence of a “preexisting” condition must also be discussed whenever a family is contemplating more refined testing. Such risks have been reduced in the US with the enactment of the Genetic Information Nondiscrimination Act of 2008 (GINA), but still remain of concern (206).

What is clear is that at present genotyping is not appropriate as a clinically applied screening tool for the general population. Approximately 50% of the nondiabetic population has the same HLA-DR types as patients with type 1 diabetes. Thus, at least 98% of the people with DR3 or DR4 will never develop type 1 diabetes. For every 1000 persons with HLA-DR3 or DR4 in the population, only two to four will develop type 1 diabetes in their lifetimes (see Table 86-6). While GWAS have identified many more genetic loci that contribute to risk, the overall ability to predict individuals who will go on to develop type 1 diabetes remains far from ideal (207).

In order for risk prediction to become appropriate, a mechanism for intervening to delay or prevent diabetes onset is needed. A few decades ago, there was great hope that such interventions were close to reality. A variety of clinical trials were undertaken to test various methods of intervention to prevent or delay the onset of type 1 diabetes, including the Diabetes Prevention Trial (DPT-1) (USA), Type 1 Diabetes Prediction and Prevention Project (DIPP) (Finland), European Nicotinamide Diabetes Intervention Trial (ENDIT), European Paediatric Pre-diabetes Subcutaneous Insulin Trial (EPP-SCIT), and the Finnish Trial to Reduce IDDM in the Genetically at Risk Study (TRIGR) (208–212). Unfortunately, many of these efforts have been proved to be ineffective and the future of type 1 diabetes prevention is less hopeful. A few prevention studies continue, however, including ones involving oral insulin (NCT00419562; NCT00336674) and teplizumab (NCT01030861) (<http://www.clinicaltrials>).

**TABLE 86-6 Risks for Type 1 Diabetes**

<b>Population risks</b>	
Overall	1/500
<b>HLA-DR related</b>	
No high risk allele	1/5000
One high risk allele (i.e. DR3/x or DR4/x)	1/400
HLA-DR4 subset defined by molecular techniques	1/300
HLA-DR3/3 or DR4/4	1/150
HLA-DR3/4	1/40
<b>Risks in relatives</b>	
<b>Siblings</b>	
Overall	1/14
<b>HLA haplotypes shared with diabetic sibling</b>	
0 haplotypes shared	1/100
1 haplotypes shared	1/20

[gov/ct2/home](http://gov/ct2/home)). More trials are underway in newly diagnosed diabetic subjects (reviewed in (213)).

**86.4.11.1 Screening for Other Autoimmune Disorders.** Diabetes is not the only autoimmune disorder for which relatives of an individual with type 1 diabetes are at risk. Family members, as well as the diabetic patient, are at an increased risk for autoimmune thyroid disease (Hashimoto thyroiditis, Graves' disease), pernicious anemia secondary to autoimmune gastritis, autoimmune adrenal disease (Addison's disease), myasthenia gravis, vitiligo, and celiac disease (214,215). A study looking at individuals with type 1 diabetes and their relatives found that 21% of the diabetics and 22% of their first-degree relatives had evidence of autoimmune disease (216). Of patients with persistent ICA, 57% had other autoimmune conditions compared with 15% of those not found to have persistent ICA (216). About 75% of the autoimmune disease in relatives occurred in families in which there was a proband with autoimmune disease, indicating that there may be increased genetic susceptibility to other autoimmune disorders in certain type 1 diabetes families.

The most common form of autoimmune disease in families with type 1 diabetes is thyroid disease (216–218). Although the proportion of type 1 diabetes patients with clinical or subclinical thyroid disease has been reported to be as high as 35%, the actual proportion is thought to be closer to 15–20% (216,219). In contrast, the prevalence of autoimmune thyroid disease in nondiabetic whites is thought to be 4.5% (218). The prevalence of clinical or subclinical autoimmune thyroid disease in first-degree relatives of individuals with type 1 diabetes is estimated to be 15–25% (216,219). As is true with autoimmune thyroid disease in the general population, female family members have higher rates of thyroid and gastric autoimmunity than do males.

Other autoimmune disorders are also seen with increased frequency in type 1 diabetic individuals and their relatives. Autoimmune gastritis, as evidenced by the detection of gastric parietal cell autoantibodies or pernicious anemia, is seen in 5–12% of individuals with type 1 diabetes and 2.5–6% of their first-degree relatives (216,219–221). The prevalence of adrenal autoantibodies is 1–3% in individuals with type 1 diabetes compared with up to 0.6% in nondiabetics (216,218).

It is particularly important for the relatives of patients with type 1 diabetes to be made aware of this increased risk for autoimmune disease, since approximately 40% of all families that include an individual with type 1 diabetes will have at least one other family member with latent or clinical autoimmune disease (216). Although most physicians know of the association of type 1 diabetes with other autoimmune disease, the fact that close relatives are also at risk is not as well appreciated in the medical community. Since many of these autoimmune disorders can have relatively insidious onsets, with fairly nonspecific symptoms, making the relatives and their

physicians aware of the increased risk may lead to earlier diagnosis and treatment.

Given this increased risk for autoimmune diseases, periodic screening of individuals with type 1 diabetes and all their first-degree relatives is warranted, particularly for thyroid dysfunction (via standard tests such as obtaining T4 and TSH levels) and for vitamin B12 deficiency, which if untreated, leads to pernicious anemia.

**86.4.11.2 Pregnancy and Type 1 Diabetes.** There is a markedly increased risk of congenital anomalies in the offspring of women with type 1 diabetes (222,223). In the general population, the risk to have a child with a birth defect is 2–3%, whereas for women with type 1 diabetes, the risk is increased threefold i.e. 6–10% (224–226). The malformations seen in infants born to diabetic women tend to be more severe than those seen in infants of nondiabetic women and include abnormalities of the skeletal, renal, cardiac, and central nervous systems (Table 86-7) (225,227–231). Virtually all anomalies occur with increased frequency in infants of diabetic mothers but those that have the highest relative risks are caudal regression, renal agenesis, transposition of the great vessels, ventricular septal defects, atrial septal defects, situs inversus, focal femoral hypoplasia/unusual facies, and neural tube defects (anencephaly and meningomyelocele). Although these malformations are generally not specific for diabetes, caudal regression is seen much more often in infants of diabetic mothers than in the general population. The relative risk for caudal regression in the offspring of a diabetic woman has been estimated to be as high as 200 (228). The relative risks for the other defects are not as high, due in large part to their higher incidence in the general population (227).

The disruption of embryogenesis leading to the abnormalities occurs before the eighth week of pregnancy (i.e. often before a woman realizes that she is pregnant) (232). There is evidence to suggest that elevated glycosylated hemoglobin (HbA1c) levels are associated with a high risk for malformations, and vigorous control of

blood glucose levels before conception has been shown to significantly reduce the incidence of congenital malformations (233–236). Although it is beneficial to optimize diabetes control even in women who present when they are already pregnant, postconceptional intervention is less likely to reduce the malformation risk (232,237). Beginning in early adolescence, diabetic women of child-bearing age should be made aware of the risk of congenital malformations and counseled that planning their pregnancies is essential so that optimal metabolic control of their disease can be achieved before conception and continued throughout their pregnancy.

Because of the increased risk for major structural malformations, prenatal diagnostic tests should be recommended for all pregnant women who have type 1 diabetes. These should be performed during the second trimester (usually between 16 and 20 weeks gestation), providing women with abnormal results the opportunity to obtain genetic counseling regarding the anomaly (i.e. prognosis and treatment options) and to make informed decisions regarding pregnancy options. For women who have normal results, the information obtained via prenatal diagnosis can be very reassuring and help alleviate anxiety for the remainder of the pregnancy. Ultrasonography can be used to evaluate fetal growth and to rule out major fetal structural anomalies such as renal agenesis, neural tube defects, and caudal regression. Fetal echocardiography, performed at 16–22 weeks following the first day of the last menstrual period, enables prenatal diagnosis of major structural cardiac malformations. Elevations of maternal serum alpha-fetoprotein (MSAFP) are associated with open neural tube defects such as anencephaly and meningomyelocele (238,239); thus, MSAFP, ideally incorporated into triple marker screening (with  $\beta$ -HCG and estriol), is recommended for all pregnant diabetics. Because MSAFP levels are altered in pregnant diabetics compared to nondiabetics, tables specific for diabetic women must be used when calculating their MSAFP values and it is therefore important that the laboratory performing the assay be made aware that the patient is diabetic (240–242). There is good evidence from the general population that folic acid supplementation, begun before conception, is helpful in decreasing the risk for neural tube defects (243–246). Although studies looking specifically at infants of diabetic mothers have not been reported, folic acid supplementation before conception should be strongly considered, as the potential benefits (i.e. reducing the risk of neural tube defects and possibly cardiac defects as well) outweigh any known risks (247).

## 86.5 TYPE 2 DIABETES MELLITUS

### 86.5.1 Introduction

Type 2 diabetes is characterized by a relative disparity between endogenous insulin production and insulin requirements, leading to an elevated blood glucose. In

contrast to type 1 diabetes, there is always some endogenous insulin production in type 2 diabetes; many type 2 patients have normal or even elevated blood insulin levels. The disease usually occurs in persons over the age of 40 years, although occurrence in childhood is increasingly recognized, and the onset may be insidious, or even clinically inapparent. The hyperglycemia of type 2 diabetes can often be controlled by diet or oral hypoglycemic agents, although exogenous insulin may be required. Type 2 diabetes continues to increase in frequency and is considered a rising epidemic worldwide (248). It has been estimated that one in every three individuals (one in two minorities) born in the United States in the year 2000 will develop diabetes in their lifetime (249), mainly due to the epidemic of obesity.

The primary pathogenetic lesion in type 2 diabetes has yet to be discovered. Primary insulin resistance of the peripheral tissues has been suggested by many as the initial event. Similarly, insulin secretion abnormalities have been argued as the primary defect in type 2 diabetes. It is likely that both phenomena are important in the development of type 2 diabetes, and genetic defects predisposing to both are likely to be important contributors to the disease process. In the most commonly accepted pathogenetic model, insulin resistance initially develops and induces compensatory insulin hypersecretion to maintain normoglycemia. Diabetes develops only when the pancreatic beta cells become, over time, unable to secrete enough insulin to overcome peripheral insulin resistance. Type 2 diabetes is a progressive disorder in that beta cell function declines with increasing duration of diabetes. GWAS in recent years appear to suggest that failure of insulin secretion is the key event that initiates type 2 diabetes; most diabetes loci discovered by GWAS appear to compromise insulin secretion or pancreatic beta cell development.

**86.5.1.1 Evidence of a Genetic Contribution to Type 2 Diabetes.** Several lines of evidence suggest the importance of genetic susceptibilities underlying the development of type 2 diabetes (250). Genetic epidemiological studies provide convincing descriptive data including population and ethnic differences, studies of familial aggregation, familial transmission patterns, and comparisons of twin concordance rates. Animal models of type 2 diabetes and studies of specific genetic syndromes that feature glucose intolerance provide further data supporting the etiologic role of genetic factors in the pathogenesis of type 2 diabetes. Finally, the genetic etiologies for type 2 diabetes have also been supported by association and linkage studies of genetic markers in populations and families.

**86.5.1.2 Evidence from Animal Models.** Relevant animal models provide the opportunity to study genes and pathophysiological mechanisms that may have application to human diabetes. Variability in blood glucose levels occurs between different strains of inbred mice and rats (251). Among the more intensively studied

mouse models of type 2 diabetes are the ob/ob (obesity and hyperglycemia) and db/db (diabetic obese) mice (252,253). The diabetes and obesity seen in conjunction with these two mutations are modified by the genetic background of the strain of mouse in which they occur (254,255). In the ob/ob mouse, the obesity and diabetes phenotype results from a nonsense mutation that generates a stop codon in the gene for the hormone leptin. The db/db mouse model has resistance to the ob gene product because of mutation in the leptin receptor (256,257). As with leptin, mutations in the leptin receptor are extremely rare in humans (258).

Several other animal models have been proposed as being more relevant to the human condition. These include the C57BL/6 J mouse strain (without leptin or leptin receptor mutations) (251,259–261), the NSY mouse (262), the TSOD mouse (263), which manifests both obesity and diabetes, and the SHR/N-cp rat (264,265). Multiple genes appear to be involved in causing diabetes in these models, similar to the apparent multigenic etiology of type 2 diabetes in humans. Investigation in these rodent models has only very rarely implicated loci that may affect type 2 diabetes in humans (266).

**86.5.1.3 Evidence from Population Studies.** Population-based studies of the distribution of a phenotypic trait can be helpful as a first step in evaluating whether the trait is likely to be controlled by a “major gene” or by multiple factors (either genetic or environmental). Several studies suggest that in populations with a high prevalence of type 2 diabetes, the distribution of glucose tolerance may be bimodal; that is, fasting glucose levels appear to be distributed around two distinct mean values. For example, in the Pima Indians, the Oklahoma Seminoles and several South Pacific populations, the distribution of glucose tolerance values in adults is consistent with an underlying bimodal distribution (259,267–269). This is usually interpreted as suggesting that there is a major gene that influences glucose tolerance, although these data are also consistent with more than one major gene. However, in most populations, blood glucose values in the population appear to be distributed unimodally. This is likely due to the heterogeneous nature of most other populations under study.

**86.5.1.4 Evidence from Twin Studies and Family Studies.** Studies in twins and families have long suggested a “genetic,” or at least a strong familial component, to the susceptibility to type 2 diabetes. MZ twin studies demonstrate very high concordance for type 2 diabetes in the twin pairs (62), yet the overall familial aggregation of clinical disease or glucose levels is not consistent with a single, simple mode of inheritance (270). Genetic heterogeneity would seem the most likely explanation and is supported by recent GWAS findings. In addition, exposure to environmental factors is known to be important as well. The identical twin data, with 70–90% concordance in MZ twins, suggest that, in the urbanized Western world, the environment is sufficiently

constant (and diabetogenic) such that genetic susceptibility is the primary determinant for the development of type 2 diabetes. In studying a specific phenotype hypothesized to be related to type 2 diabetes development, Tremblay and coworkers (271) found tentative evidence for genetic factors influencing sensitivity of insulin levels with physical training in response to short-term exercise in male MZ twin pairs.

**86.5.1.5 Difficulties in Studying the Genetics of Type 2 Diabetes.** Type 2 diabetes and other common chronic diseases present a number of difficult analytic challenges to the geneticist. The late and variable age of onset of type 2 diabetes, probably resulting from interactions of both genetic and environmental factors, can result in an underestimation of the number of individuals who are genetically susceptible to type 2 diabetes. This is a particularly vexing problem for family studies, in which linkage of type 2 diabetes with genetic markers is often the goal. While there is typically no confusion about the status of an affected living individual, unaffected individuals who carry the requisite gene(s), but who have not yet lived long enough to express diabetes, will not be recognizable. In addition, at the time a family is studied, many affected members in the older generations will be deceased and may have had their diabetes diagnosed (or not diagnosed) years ago, using perhaps less-than-optimal diagnostic criteria. The late age of onset also means that some individuals who are genetically “affected” will die of other causes before developing diabetes.

Another difficulty in studying the genetics of type 2 diabetes is the strong environmental component involved in many forms of diabetes. In industrialized or “westernized” countries, high MZ twin concordance rates suggest that the environment is sufficiently uniform (and diabetogenic) such that most individuals with the genetic predisposition will develop diabetes. On the other hand, in nonwesternized countries, studies of the genetics of type 2 diabetes are far more difficult to carry out. Many people with the requisite genes will simply never have the opportunity to manifest clinical disease under existing environmental conditions.

Studies in migrant populations that have had a rapid change in diet and/or exercise levels give some indication of the strength of the environmental component in the etiology of type 2 diabetes. For example, among the Nauruans of the South Pacific, documented prevalence of diabetes has increased from low rates to more than 50% of the adult population in a time period of about 30 years (272). Similar increases in prevalence with westernization have been noted in other populations as diverse as the natives of Australia, Africa, and Near Eastern immigrants to Israel, Japanese immigrants to the United States, and certain Native American populations (273–276).

Perhaps the most problematic aspect of studying the genetics of type 2 diabetes is the likely extensive etiologic

heterogeneity that underlies this disease. Genetic defects could (and probably do) influence any of the many steps involved in glucose regulation. Each of these defects, either alone or in concert with other defects, could result in type 2 diabetes. While such etiologic complexity by no means precludes genetic investigations, extensive etiologic heterogeneity implies that to understand particular pathogenetic mechanisms, one must be able to measure physiological “defects” at a more specific level than the gross phenotype of glucose intolerance.

### 86.5.2 Genetics of Intermediate Phenotypes for Type 2 Diabetes Mellitus

The study of physiological traits associated with type 2 diabetes within families can be useful in several levels, including dissection of disease heterogeneity. First, it may allow characterization of early stages of, and variability in, the natural history of the disease. It also allows for comparison between families, which may be helpful in separating etiologic subtypes. Finally, it can lead to better studies of mode of inheritance and linkage to genetic markers, as more of the genetically “affected” individuals in the pedigree will be identified. Another advantage of the study of intermediate phenotypes is that they may more closely reflect underlying genetic defects that predispose to disease.

The first physiological studies in families with type 2 diabetes were conducted using glucose tolerance as the phenotype. Even with this relatively crude measure of glucose metabolism, there was evidence that, in normal healthy subjects, glucose and insulin responses have an appreciable genetic component (277). In their studies of large pedigrees with type 2 diabetes, Beaty and Fajans (278) also assessed the role of genetic determinants of fasting blood sugar levels. Their data were consistent with a role for additive genetic factors, although a large proportion of the intrafamilial variability could not be explained by genetic factors. Familial studies of liability for hyperglycemia in Pacific Nauruans have also been interpreted as consistent with the effect of a major gene (279). However, in studies of Japanese Americans, Williams and colleagues (280) concluded that heritability of fasting blood glucose within families was low, and they could find no evidence for a major gene. Similar results were reported from a study of families in Jerusalem (281). In contrast, a study among healthy female twin pairs found a high heritability (proportion of total trait variance that is due to genetic factors) of 0.75 for fasting glucose (282). In studies of Danish twins, the heritability of abnormal glucose tolerance was found to be 0.61; the heritabilities for women and men of fasting glucose were 0.12 and 0.38 and of 2-h postload glucose were 0.38 and 0.43, respectively (283,284).

Insulin sensitivity/resistance is known to be heritable, evidenced by the observation of reduced insulin sensitivity in nondiabetic relatives of subjects with type 2

diabetes (285,286). Fasting insulin level is a simple surrogate measure of insulin sensitivity/resistance. Studies in the Mexican American population, a high-risk population with a high prevalence of type 2 diabetes, have demonstrated a genetic “dosage effect” on fasting insulin levels (287). An increase in fasting insulin levels was a function of whether an individual had 0, 1, or 2 diabetic parents, suggesting that insulin resistance is familial. Reported estimates for the heritability of fasting insulin range from 0.17 (288) to 0.38 (289) to 0.53 (290,291). In addition to genetic differences between populations studied, this wide range may reflect the fact that fasting insulin is determined not only by insulin sensitivity but also by insulin secretion and insulin clearance, each of which appears to be genetically determined (289).

Insulin sensitivity may also be more directly quantified by physiological phenotyping procedures used in research settings, such as the euglycemic hyperinsulinemic clamp, the frequently sampled intravenous glucose tolerance test, or the insulin suppression test (292). In an elegant study in Pima Indians (another high risk group), Lillioja and associates (293) demonstrated using the euglycemic clamp that in vivo insulin action has a familial component. Glucose uptake at maximally stimulating insulin concentrations showed a high degree of familiarity that was independent of age, sex, or degree of obesity. To control for familial correlations in dietary intake, subjects were placed on a standard diet for at least 7 days. Thus, the “familial” component, which was estimated to explain 38% of the variance in insulin action, appeared to be due to genetic rather than environmental similarities. Other studies utilizing the euglycemic clamp, widely considered to be the “gold standard” in quantification of insulin sensitivity, found heritabilities of 0.37–0.55 (289,294–296). The heritability of insulin sensitivity, quantified by the frequently sampled intravenous glucose tolerance test ranged from 0.28 to 0.44 (278,297,298).

Besides insulin resistance, an abnormality in insulin secretion is present in people with type 2 diabetes. Genetic/environmental influences on the insulin response to glucose were studied at the Karolinska Hospital in Sweden (299,300). In studying insulin release after a glucose infusion in family members, as well as fasting and stimulated glucose and insulin levels, these researchers first concluded that their data showed considerable intrafamilial correlation and was consistent with a major recessive gene common in the Swedish population (with a gene frequency perhaps as high as 20%) (299). More recent studies of insulin release and sensitivity in these families still suggest that these variables are genetically regulated, although the evidence for a major gene is no longer as convincing (300). The studies of Haffner and colleagues (301) in both Mexican American and non-Hispanic whites have also provided evidence that insulin secretion is likely genetically influenced, as a family history of diabetes was associated with decreased insulin secretion in response to an oral glucose load, as well as

with fasting insulin levels. Other studies have also looked at physiological abnormalities of insulin secretion in relatives of diabetics (302). For example, O’Rahilly and colleagues (303) studied the normal pulsatile release of insulin in first-degree relatives of type 2 diabetes subjects. Compared to controls, the first-degree relatives lacked the normal oscillations in insulin secretion following an intravenous glucose challenge. Since these relatives had mild glucose intolerance and high normal fasting glucose levels, this lack of pulsatile insulin release may be the first expression of type 2 diabetes in these high-risk relatives (304). Heritability estimates for insulin secretion range from 0.25 to 0.57 as determined from insulin measurements during oral glucose tolerance testing (283,284,305) and 0.23 to 0.84 as determined from intravenous glucose tolerance tests (277,296,297,306–308).

The genetic basis of the previously mentioned intermediate traits is supported by the fact that linkage signals for these traits have been detected in genome-wide scans. The Insulin Resistance Atherosclerosis (IRAS) Family Study found linkage of both fasting glucose and fasting insulin with a locus on chromosome 17p (309). The same study found linkage peaks for insulin secretion on chromosomes 4q, 11q, and 12q; insulin sensitivity index was linked to chromosome 15p (310). The insulin secretion linkage to 4q was replicated by the HERITAGE Family Study, which also identified another locus for insulin secretion on 10p (311). The Finland-United States Investigation of Non-insulin Dependent Diabetes Mellitus Genetics (FUSION) study also found linkage of insulin secretion to 10p, as well as 9p (312).

### 86.5.3 Evidence Supporting Heterogeneity in Type 2 Diabetes

When surveys of glucose tolerance have been performed in populations of European ancestry, the number of individuals found to have latent (subclinical) diabetes has been approximately equal to that with known diabetes. Among the Eskimos, however, clinical diabetes is extremely rare, but abnormal glucose tolerance tests have been found to be very common (313). Thus, abnormal glucose tolerance in the Eskimo appears to be a biochemical trait that rarely leads to clinical diabetes. The maximum plasma insulin response to an oral glucose challenge in healthy Navajo and Pima Indians was over three times as great as that observed in Western Europeans (314,315). In addition, the insulin output of type 2 diabetics was also clearly different in the American Indians than in the Europeans. Physiological studies of Asian Indians with type 2 diabetes suggest that they are more insulin resistant than are whites with type 2 diabetes, even when the degree of obesity is comparable (316). These data raise the possibility that there may be distinct subtypes of type 2 diabetes in different populations or ethnic groups and that it is possible that these differences are genetically determined.

Even early clinical genetic studies suggested heterogeneity within type 2 diabetes. When Kobberling (317) divided his adult-onset probands into low, moderate, and markedly overweight categories, he found a significantly higher frequency of affected siblings in the light-proband category (38%) and a significantly lower frequency in the heavy-proband category (10%). Irvine and colleagues (318) also suggested a difference between nonobese and obese insulin-dependent probands. They observed a different clinical range of diabetes in the relatives of the nonobese and obese probands.

Fajans and coworkers (319) have demonstrated metabolic heterogeneity in nonobese latent diabetes. These investigators were able to divide their latent diabetic patients into two broad groups: those with an insulinopenic form of glucose intolerance and those with high levels of plasma immunoreactive insulin. The high responders and low responders remained consistent and distinct over many years of follow-up, suggesting that they represented different metabolic disorders.

There is remarkable variability in the physiological abnormalities seen in patients with type 2 diabetes, ranging from structural and numeric abnormalities of pancreatic alpha and beta cells to abnormalities in pancreatic insulin secretion and decreased insulin sensitivity in the pancreas and peripheral tissues. There is considerable evidence for even further physiological heterogeneity in type 2 diabetes (320). For example, among patients with mild type 2 diabetes or impaired glucose tolerance are individuals with early insulin responses that range from supernormal to subnormal. Similar variability has been documented for the late insulin response in such patients (320). Because so much variability is seen in individuals with presumably early states of diabetes, it strongly suggests that type 2 diabetes is not caused by a single defect. Genetic studies, as discussed later, support this notion.

### 86.5.4 Genetic Approaches in Type 2 Diabetes

In dealing with heterogeneity in type 2 diabetes, there are several possible research strategies that can potentially be employed. In general, there are three options: (1) start with observable physiological differences and then work backward to determine if these differences can be explained by different genetic defects (working from the phenotype down); (2) start with a candidate gene or allele proposed to be related to diabetes, establish a genetic relationship, and work forward (working from the genotype up) to determine if specific physiological traits are associated with this gene or gene defect; and (3) use genome-wide linkage or GWAS approaches to identify chromosomal regions likely to contain diabetes-related traits or clinical diabetes itself and then assess if there are detectable physiological differences between those individuals (or families) displaying linkage and/or linkage disequilibrium and those individuals or families

that do not appear to be linked to the particular genomic locus. In actuality, research often involves the sequential application of all these approaches, as is well demonstrated by the investigations of MODY.

### 86.5.5 Maturity Onset Diabetes of the Young

MODY was originally described in 1964 (321) and was clearly identified as an autosomal dominant subtype of type 2 diabetes in the 1970s (322). In addition to the criteria for the diagnosis of diabetes, the MODY diabetic must meet the following additional criteria: (1) age of onset for at least one family member under 25 years; (2) correction of fasting hyperglycemia for at least 2 years without insulin; and (3) nonketotic diabetes (322). Using these criteria, many families with clearly dominant inheritance have been identified. However, there is considerable clinical heterogeneity within MODY, which is now appreciated to be due in large measure to genetic heterogeneity. In the French population, using rather stringent criteria, it is estimated that MODY may account for as much as 10–15% of familial diabetes cases, but less of general or later-onset type 2 diabetes (323). Although MODY is a relatively rare disorder, accounting for approximately 2–5% of all type 2 diabetes cases, it has taken on great importance in the past decade because of the lessons it has taught about the loci involved in type 2 diabetes and genetic heterogeneity.

The first MODY locus was identified by Bell and colleagues (324), with the demonstration of linkage of MODY with the adenosine deaminase (ADA) locus on the long arm of chromosome 20 in one large MODY family (the RW pedigree). Interestingly, clear delineation of linkage was only possible after exclusion of certain branches of the RW pedigree from analysis, following appreciation of the fact that non-MODY type 2 diabetes was occurring in these branches. The responsible gene is HNF-4 $\alpha$  (325); to date only a handful of MODY families have mutations in HNF-4 $\alpha$ , suggesting that this locus (MODY1) accounts for a minority of MODY subjects.

Not long after linkage to chromosome 20 was reported, linkage in other MODY families was reported with the glucokinase gene (GCK) on chromosome 7p (326,327). Unlike the ADA locus on chromosome 20, which was tested simply as a polymorphic marker in a systematic mapping approach, GCK was tested as a candidate gene because of its role in glucose homeostasis (323,328,329). Most MODY patients have a decreased insulin response to glucose, suggesting a primary pancreatic beta cell defect (330); thus the GCK was an excellent candidate for genetic investigations. Following the demonstration of linkage, actual mutations within the coding region were identified (331–333). Mutations in GCK account for a major portion of MODY pedigrees; as high as 60% of French MODY families have GCK mutations (334).

To date, mutations in six genes have been identified that produce a MODY phenotype, with another five being proposed (Table 86-8). Mutations in HNF-1 $\alpha$  (MODY3) are the most common form of MODY. While in most forms of MODY diabetes is the only identified abnormality, mutations in HNF-1 $\beta$  are also associated with serious renal defects and sometimes also with genital anomalies (Mullerian aplasia) (335–338). Heterozygous mutations in IPF1 cause MODY, whereas homozygous mutations produce pancreatic aplasia or hypoplasia and neonatal diabetes requiring insulin treatment (339,340). The severity of diabetes varies depending on which gene is altered; defects in the hepatocyte nuclear factor genes result in much more serious, often insulin-requiring, diabetes than is seen with GCK mutations. Unlike classical type 2 diabetes, the predominant abnormality leading to diabetes resulting from MODY gene mutations lies in insulin secretion, with insulin resistance not being a significant factor.

Heterozygous GCK mutations cause a relatively mild form of diabetes or only impaired glucose tolerance in most affected individuals. The prevalence of frank diabetes compared with impaired glucose tolerance is less than 50% (341). They rarely require insulin and usually do not develop vascular complications (342). Mutations in GCK are thought to alter the set point of the beta cell so that a higher circulating glucose level is necessary to trigger insulin secretion (343). The much rarer homozygous GCK mutations result in permanent neonatal diabetes requiring insulin therapy (344).

Even with the identification of six (and perhaps eleven) genetically distinct forms of MODY, there may be additional MODY loci to be found. Approximately 15–20% of MODY in England and France, and an even higher proportion in Japan, does not result from mutations in any of the known MODY genes (345). Given that several genes are able to cause MODY, it is not surprising that even greater genetic heterogeneity has been observed within “classical” type 2 diabetes. Just as different MODY defects appear to cause varying degrees of diabetes severity and complications, the clinical and physiological differences among type 2 diabetes patients may well result from genetically separate forms of diabetes.

### 86.5.6 Candidate Genes and Type 2 Diabetes

A large number of candidate genes have been tested for possible roles in the etiology of type 2 diabetes with mostly negative results. Many associations initially reported were not reproduced in other studies; this may be a result of false-positive studies, false-negative studies, or true variability in association among different populations, wherein a variant may alter diabetes risk differently depending on the genetic and/or environmental characteristics of the particular population (120). Those genes with the strongest evidence of association

TABLE 86-8 Genes that Can Cause Maturity-Onset Type Diabetes			
Locus	Chr	Gene	Function
MODY 1	20	Hepatocyte nuclear factor-4 $\alpha$ (HNF4, TCF14)	Expressed in liver, kidney, intestine, and pancreatic islets Member steroid/thyroid hormone receptor superfamily A key regulator of pancreatic gene expression, it is an upstream activator of HNF-1 $\alpha$ expression
MODY 2	7	Glucokinase (GCK)	First step in glycolysis; phosphorylates glucose/glucose-6-P; functions as glucose sensor in beta cells by controlling glucose entry to glycolysis; expressed in beta cells and liver
MODY 3	12	Hepatocyte nuclear factor 1 $\alpha$ (HNF 1A; TCF1)	Transcription factor in liver, kidney and $\beta$ -cell Weak activator of transcription of the rat insulin gene; impaired dimerization may be the cause of beta cell dysfunction; associated with a more severe insulin secretory defect than seen in MODY2
MODY 4	13	Insulin promoter factor (IPF1)	Key regulator of islet peptide hormone expression and also responsible for development of the pancreas, likely by determining maturation and differentiation of pancreatic precursor cells in the developing gut. Heterozygous mutations cause MODY; homozygous mutations cause pancreatic agenesis
MODY 5	17	Hepatocyte nuclear factor-1 $\beta$ (HNF1B; TCF2)	Transcription factor in liver, kidney and $\beta$ -cell Associated with renal abnormalities (nephron agenesis, hypoplastic glomerulocystic disease, severe nephropathy leading to renal failure and genital anomalies)
MODY 6	2	Neurogenic differentiation 1 or beta cell E-box trans-activator 2 (NEUROD1; BETA2)	Transcription factor required for normal development of pancreatic beta islets; Transcriptional activator of insulin gene
MODY 7	2	Kruppel-like factor 11	Transcription factor that activates the insulin gene
MODY 8	9	Carboxyl-ester lipase	Major component of pancreatic juice. Mutation leads to diabetes and pancreatic exocrine dysfunction, suggesting a link between exocrine and endocrine pancreatic function
MODY 9	7	Paired box gene 4	Transcription factor involved in $\beta$ -cell development
MODY 10	11	Insulin	Rare missense mutations in the insulin gene have led to MODY in a few families. Some affected members had mild diabetes initially controlled by oral agents, followed by insulin
MODY 11	8	B-lymphocyte specific tyrosine kinase	Expressed in $\beta$ -cells, where it colocalizes with insulin. Overexpression in islets enhanced insulin secretion in high glucose conditions

MODY, maturity-onset diabetes of the young.

are peroxisome-proliferator-activated receptor gamma (PPARG), the pancreatic beta cell inwardly rectifying potassium channel Kir 6.2 (KCNJ11), transcription factor 2, hepatic (TCF2, also known as HNF1B), and wolfram syndrome 1 (WFS1). Of note, rare, severe mutations in all four of these genes lead to syndromic diabetes, and two of these genes (PPARG, KCNJ11) code for proteins that are targets of oral antidiabetic medications. PPARG codes for the nuclear hormone receptor transcription factor PPAR- $\gamma$ , which is highly expressed in adipose tissue and plays a role in adipocyte differentiation and insulin sensitivity. A common variant, Pro12Ala, is associated with diabetes, with increased risk conferred by the more frequent proline allele (odds ratio 1.2). While the effect on diabetes is modest, the frequency of the proline allele may translate to a large population-attributable risk, which has been estimated as high as 25% (346,347). PPARG is the target of the thiazolidinedione class of oral antidiabetic agents used in type 2 diabetes.

The pancreatic beta cell potassium channel encoded by KCNJ11 codes for Kir6.2, which complexes with the product of ABCC8 (also known as SUR1, sulfonylurea receptor-1) to form the pancreatic beta cell potassium channel whose function governs insulin secretion. This channel is closed in response to the ATP generated when glucose enters glycolysis in pancreatic beta cells; the closure of this channel leads to exocytosis of insulin. Sulfonylureas bind to and close these channels, triggering insulin release. Rare mutations in KCNJ11 cause monogenic syndromes; activating mutations can cause transient or permanent neonatal diabetes, and inactivating mutations can cause persistent hyperinsulinemic hypoglycemia of infancy. In terms of common type 2 diabetes, the lysine allele of the common Glu-23Lys variant in KCNJ11 has been found to confer an odds ratio of 1.4 for diabetes (348). This allele has also been associated with impaired insulin response during oral glucose tolerance testing, supporting its effect on insulin secretion.

The most recently identified candidate genes for type 2 diabetes were previously known for their role in monogenic diabetes syndromes, TCF2 with MODY 5 and WFS1 with Wolfram syndrome (also known as DIDMOAD, diabetes insipidus, diabetes mellitus, optic atrophy, and deafness). While rare missense variants in these genes cause these syndromes, noncoding variants in or near these genes contribute to risk of common type 2 diabetes (349–351), most likely via an effect on beta cell development or survival (352). TCF2 is a transcription factor that may play a role in pancreatic beta cell development. Expressed in the brain and pancreas, WFS1 codes for an integral membrane glycoprotein that localizes primarily in the endoplasmic reticulum, where it regulates calcium fluxes.

Of note, the odds of diabetes in carriers of particular variants in these genes ranges from 1.1 to 1.2 (348,352,353); such moderate effects are detectable only

by sufficiently powered studies. This likely contributed to the limited success of the candidate gene approach.

### 86.5.7 Identifying Type 2 Diabetes Genes by Genome-Wide Linkage Scans

Given that candidate gene studies did not appear to explain the majority of genetic susceptibility to type 2 diabetes, there was great hope that the advent of genome-wide linkage analyses would finally allow the major loci involved in type 2 diabetes to be identified. While some potential loci have come from these approaches, the yield has been much less than was initially anticipated. To date, dozens of genome-wide linkage scans have been performed to identify loci for type 2 diabetes and have led to the identification of only two diabetes genes. Many other loci for type 2 diabetes have been suggested, with the strongest evidence across studies for loci on chromosomes 1q and 20q.

The first locus reported from a genome scan was NIDDM1 on chromosome 2 (354). This study was performed in Mexican American sib pairs and subsequent searches in non-Hispanic populations were unable to confirm this locus (355–358). However, Horikawa and coworkers (359) reported the identification of calpain 10 (CAPN10) as the gene on distal chromosome 2 responsible for the NIDDM1 linkage previously reported. Their studies suggested that a particular haplogenotype (termed 112/121, composed of three intronic variants) accounts for type 2 diabetes susceptibility attributable to this locus. Since the original publication, a large number of reports examining association of CAPN10 variants with type 2 diabetes and related insulin and glucose traits have been published, with many, but not all, suggesting a role for CAPN10 in diabetes pathogenesis. Notably, comprehensive meta-analyses support association of particular intronic variants with type 2 diabetes (360,361). Whether these intronic variants are functional or are linked to functional variation elsewhere in the gene is unknown. No CAPN10 variants have been identified as associated with type 2 diabetes by GWAS.

In 2006, TCF7L2 (transcription factor 7 like 2), the locus with the strongest effect on the risk of type 2 diabetes, was discovered by investigators who were following up a linkage signal found on chromosome 10 in Icelandic individuals (362). Each risk allele at this locus confers a 1.4 odds of type 2 diabetes in Europeans; the 7% of Europeans with two risk alleles have double the diabetes risk compared to the 55% of individuals with no risk alleles (363). A large number of subsequent studies reproduced association of TCF7L2 variation with type 2 diabetes, not only in Europeans but also in other racial/ethnic groups (364). The actual variants that influence diabetes may differ by racial groups (365,366). TCF7L2 diabetes alleles are associated with reduced insulin secretory response to oral or intravenous glucose in nondiabetic individuals (367–370). TCF7L2,

a nuclear receptor for beta-catenin, is a component of the Wnt signaling pathway; as such, it may regulate cell proliferation, motility, cancer, myogenesis and/or adipogenesis (371). TCF7L2 transactivates the insulin and proglucagon genes, the latter codes for both glucagon and the incretin hormone glucagon-like peptide-1 (GLP-1), which potentiates glucose-stimulated insulin secretion. Impairment of these systems is a likely mechanism whereby variants in TCF7L2 reduce insulin secretion (372–374).

Another locus of interest from the genome scans is located on the long arm of chromosome 1. This locus is near a “diabesity” locus mapped in the Pima (375). Linkage of 1q with type 2 diabetes and related phenotypes has been demonstrated in numerous populations, including whites and African Americans, French whites, United Kingdom whites, Old Order Amish, Chinese, Hispanics, Pima Indians, and Utah whites (311,356,375–381). Notably, the region of the rat genome that is syntenic to human 1q has been linked with glucose tolerance and fasting insulin level in genome scans in the Goto Kakizaki diabetic rats (382,383). The fact that this is an often-replicated locus for type 2 diabetes led to the formation of the International 1q Consortium, whose goal is to identify the responsible gene(s). Recently, the Consortium fine-mapped a 23-Mb region of 1q, finding signals in the NOS1AP and ASH1L/PKLR regions that subsequently did not replicate association with type 2 diabetes (384). A weak effect of variation in NOS1AP was subsequently found in a Chinese study (385).

Linkage has also been reported between type 2 diabetes and the MODY1 region on chromosome 20 in a number of white populations (386–389), as well as Japanese (390). Linkage of 20q with diabetes was not demonstrated in other studies (391). Linkage of this region of 20q with fasting insulin was also reported in a Chinese population (392). While Hani and coworkers (393) reported an HNF-4 alpha mutation in one family with late-onset type 2 diabetes, other HNF-4 alpha mutations have only been found in classical MODY pedigrees. It thus appears that the type 2 diabetes locus on chromosome 20 is likely separate from HNF-4 alpha. Fine mapping of the 20q region in Japanese cohorts also did not implicate HNF-4 alpha in type 2 diabetes (394,395).

The genome-wide linkage scans performed to date in type 2 diabetes and other multifactorial disorders have yielded few susceptibility genes. Even when linkage to a chromosomal region is firmly established, determining which gene and which sequence variant within or nearby that gene are responsible for diabetes susceptibility has been challenging. The advent and application of GWAS has been much more productive. Virtually none of the type 2 diabetes loci discovered by GWAS have corresponded to linkage signals (396), suggesting that linkage might be explained by rare variants of high effect (or other types of genetic variation), rather than common variation typically covered by GWAS.

### 86.5.8 Type 2 Diabetes Genes Identified by Genome-Wide Association Studies

GWAS have resulted in the discovery of a dramatic number of genes for type 2 diabetes (Table 86-9). This was facilitated by cooperation between multiple centers, both in the acquisition of large numbers of cases and controls and in data sharing to confirm association signals. The first wave of GWAS in type 2 diabetes consisted of five studies published in 2007, all of which were conducted in European-origin subjects (Finnish, French, British, Swedish, Icelandic) (397–401). The loci identified included polymorphisms in or near HHEX/IDE, SLC30A8, CDKAL1, CDKN2A/2B (2 independent signals), and IGF2BP2. FTO was identified as a locus for body mass index (BMI) and type 2 diabetes via the GWAS that did not match diabetes cases and controls for BMI (398,401) and confirmed in other GWAS (402,403). In 2008, three of the groups behind the initial studies, the Wellcome Trust Case Control Consortium (401), the Diabetes Genetics Initiative (397), and the Finland-US Investigation of NIDDM (FUSION) study (398), collaborated to conduct a GWAS meta-analysis as the Diabetes Genetics Replication and Meta-analysis (DIAGRAM) study, which discovered an additional six loci, JAZF1, CDC123/CAMK1D, TSPAN8/LGR5, THADA, ADAMTS9, NOTCH2 (404). This year also saw the first type 2 diabetes GWAS conducted in Asian populations (Japanese, Korean, Chinese, Singaporean), which identified KCNQ1, subsequently found to be associated with diabetes in Europeans as well (405,406). In Asians, KCNQ1 is the locus with the strongest effect size, comparable to TCF7L2 in Europeans. In 2009, a multistage GWAS in French, Danish, and Finnish subjects identified a variant near the IRS1 gene as associated with type 2 diabetes (407). Multiple studies following up GWAS signals for fasting glucose identified six additional type 2 diabetes loci, ADCY5, DGKB, GCK, GCKR, MTNR1B, and PROX1 (408–411). In 2010, a GWAS in Taiwanese subjects added two more genes, SRR and PTPRD (412), while two additional European meta-analyses identified 13 additional loci, RBMS1/ITGB6, BCL11A, DUSP9, KLF14, CENTD2, HMG2, HNF1A, ZBED3, CHCHD9, ZFAND6, PRC1, and a second signal in KCNQ1 (413,414). A GWAS in Japanese subjects identified C2CD4A/4B and UBE2E2 as additional diabetes loci; only the latter was also associated with diabetes in Europeans (415). A different SNP downstream of C2CD4B had previously been associated with fasting glucose (408), and the diabetogenic SNP was later found to affect glucose-stimulated insulin secretion (416). A GWAS from the Asian Consortium of Diabetes discovered a new locus near SPRY2 and identified two new signals in the CDC123/CAMK1D and C2CD4A/4B regions (417).

It is important to note that for most of these loci, the causal gene and variant have not been established; the

TABLE 86-9 Susceptibility Genes for Type 2 Diabetes							
Locus: Nearest Gene(s)	Chromosomal Location	Marker(s)	Variant Type(s)	Source of Initial Discovery	Genome-Wide Associated Trait(s)	Diabetes Effect: OR (95% CI)	Protein
ADAMSTS9	3p14.3-p14.2	rs4607103	38 kb upstream	European GWAS meta-analysis	T2DM	1.09 (1.06–1.12)	ADAM metalloproteinase; peptidase; thrombospondin type 1 motif

FG, fasting glucose; T2DM, type 2 diabetes mellitus; HbA1c, hemoglobin A1c; HOMA-IR, homeostasis model assessment of insulin resistance; HOMA-B, homeostasis model assessment of  $\beta$ -cell function; 2-h glucose level on oral glucose tolerance test.

associated variants may be in linkage disequilibrium with functional variants in the nearest gene (typically used to label the locus) or elsewhere. As displayed in Table 86-9, in most cases the associated variants are in introns or intergenic regions; only a handful of functional missense variants have been discovered. Even in the latter cases, complex scenarios are possible, for example, the Glu-23Lys variant in *KCNJ11* is strongly linked to the Ser-1369Ala variant in *ABCC8*, with both genes coding for components of the ATP-sensitive potassium channel that is critical to glucose-stimulated insulin secretion (418). Evidence suggests that the presence of both variants may lead to deficient insulin secretion (419). Also, intronic variants may prove functional, as suggested by the association of the *TCF7L2* SNP rs7903146 with open chromatin and greater enhancer activity (420).

GWAS for fasting glucose and 2-h glucose identified associations with genes previously or later found to also be associated with type 2 diabetes (e.g. *TCF7L2*, *ADCY5*, *GCKR*, see Figure 86-1); however, they also identified several genes associated with glucose only, suggesting that some genes influence glucose in the physiological range without contributing to diabetes risk (408,421). Genes with similar effect on fasting glucose, such as *ADCY5* and *MADD*, each of which has an effect of approximately 0.5 mg/dL per risk allele, may have very different effects on diabetes risk (only *ADCY5* is associated with diabetes) (408). On the other hand, a gene with a small effect on diabetes (e.g. *MTNR1B*, odds ratio 1.2 per allele) may have a large effect on fasting glucose (1.2 mg/dL per allele), whereas a gene with a strong effect on diabetes (e.g. *TCF7L2*, odds ratio 1.4 per allele) may have a smaller effect on fasting glucose (0.4 mg/dL per allele) (408). These facts point to the complexity of glucose regulation and how genes that affect glucose may or may not influence the risk of diabetes.

A similar situation is found in GWAS of hemoglobin A1c (HbA1c), which reflects average glycemia over a

2- to 3-month period. Hemoglobin A1c, used to monitor treatment response in diabetes for many years, has been recently advocated as a diagnostic tool (422). A GWAS for HbA1c found association with loci previously implicated in fasting glucose (*G6PC2*) and fasting glucose and type 2 diabetes (*SLC30A8*, *GCK*) (423). This GWAS also identified a novel locus *HK1* (hexokinase 1 expressed mainly in red blood cells), which is not associated with fasting or 2-h glucose or type 2 diabetes (423,424). Subsequent meta-analyses added *TCF7L2* and *MTNR1B* as diabetes loci that were associated with HbA1c (425,426), however, several other loci were identified that appear to influence HbA1c via nonglycemic pathways, such as anemia and iron storage (424,426). Notably, loci associated with HbA1c in studies of type 1 diabetes were not associated with HbA1c in cohorts with type 2 diabetes (427).

Type 2 diabetes is thought to arise from concurrent insulin resistance and deficient insulin secretion. Several studies, typically in nondiabetic subjects, have examined the type 2 diabetes loci for association with indexes of insulin resistance and insulin secretion. Most studies derived these traits from fasting insulin and glucose measures, via homeostatic model assessment (HOMA) indexes of insulin resistance (HOMA-IR) and beta-cell function (HOMA-%B) or via indexes derived from oral glucose tolerance testing. A minority of studies employed more sophisticated methods of quantifying insulin-related traits, such as euglycemic or hyperglycemic clamps or frequently sampled intravenous glucose tolerance tests. The overwhelming finding of these studies is that the majority of type 2 diabetes loci are associated with impaired beta-cell function, thought to act via compromised development of beta cells or defective insulin responses to glucose or to the incretin hormones (Figure 86-1). Only a few genes appear to act via insulin resistance. This was unexpected, as insulin resistance was known to be a heritable trait, and may reflect a different genetic architecture of insulin resistance (e.g. more

**FIGURE 86-1** Established loci for type 2 diabetes, fasting glucose, 2-h glucose, and insulin resistance. Those loci also associated with insulin secretion (apparent effects on beta cell development/mass or glucose/incretin-stimulated insulin release) and hemoglobin A1c are indicated with \* and †, respectively.

influenced by rare variants). On the other hand, insulin resistance may not be well reflected by the quantitative traits commonly examined (428). Alternatively, insulin resistance may be more influenced by environmental and lifestyle factors, such as diet and weight gain. The predominance of diabetes genes associating with beta cell function suggests a model wherein genetically determined robustness of the beta cell's ability to maintain compensatory insulin secretion in the face of insulin resistance is the main gateway by which subjects develop type 2 diabetes. Those individuals who maintain sufficient insulin secretion do not develop diabetes, even if substantial insulin resistance is present. Consistent with this is the fact that obesity and insulin resistance are more prevalent in the population than type 2 diabetes.

The explosion of GWAS publications had led some to question their value. As of early 2011, the over 40 genes described as associated with type 2 diabetes appear to explain only 10% of the inheritance of this disease. The unexplained approximately 90% has been called the “missing heritability.” A number of factors may ultimately account for the missing heritability. First, GWAS chips capture (via linkage disequilibrium), mainly common (frequency >5%) variation. Depending on the racial group studied, they capture 70–80% of such variation. Missed common variation notwithstanding, those loci that are identified may be in linkage disequilibrium with functional variants elsewhere; identifying those variants may explain more of the heritability. Many believe that a substantial portion of the missing heritability will ultimately be explained by rare variation with large effect sizes. Already, rare variants are being examined in diabetes genes such as TCF2, with some manifesting association with type 2 diabetes (429). Current whole-exome sequencing efforts (1000 Genomes Project, [www.1000genomes.org/page.php](http://www.1000genomes.org/page.php)) are anticipated to capture rare variation. Other factors that may account for missing heritability include the effects of gene–gene interactions, gene–environment interactions, epigenetic factors (e.g. DNA methylation and histone modification), prenatal programming, and non-SNP variation (e.g. copy number variation). Noncoding RNAs that affect gene expression may be responsible for observed associations, as suggested in the CDKN2A/2B locus (430). It is clear that GWAS, while increasing the number of diabetes genes 20-fold, are only the beginning of a complete understanding of diabetes genetics.

The diabetes genes discovered by GWAS have yet to translate to applications in clinical care. Several studies evaluating the utility of genetics to predict who may develop diabetes in the future, typically utilizing a risk score based on the total number of risk alleles, have found little incremental predictive value when added to traditional risk factors (e.g. age, BMI, gender, family history) (431–434). There is some evidence that genetic information in the prediction of type 2 diabetes may be more effective in younger adults (435).

Ultimately, the major contribution of GWAS to diabetes care may be in the development of new therapies. GWAS have led to novel insights in the pathophysiology of diabetes, and may have already identified key pharmacological targets. Two of the earliest diabetes genes, PPARG and KCNJ11, encode drug targets. It is highly likely that the many additional genes harbor one or more potential targets. Assisted by advances in technology, GWAS have discovered diabetes loci much more quickly than molecular, physiological, and pharmaceutical research are able to develop these into new drug therapies. Within the next decade, these arenas should be able to utilize genetic information to produce new treatments for diabetes. Another frontier that is likely to advance as a result of the many new genes is pharmacogenetics: use of genetic information to predict treatment response and adverse effects. Several studies have already documented effects of diabetes alleles on treatment response (436–439). In the future, once larger numbers of disease-response-predicting alleles have been elucidated, genetic testing before starting therapy may become common practice.

### 86.5.9 Mitochondrial Mutations and Maternal Transmission

In early studies of type 2 diabetes and MODY-like families, Dorner and colleagues (440,441) reported evidence that diabetes occurred more frequently on the maternal than on the paternal side of families ascertained through a diabetic proband. A study of French white type 2 diabetes patients demonstrated a significant excess of diabetic mothers and maternal relatives (aunts and uncles) compared with fathers and paternal relatives (442). Pettitt and coworkers, studying the inheritance of diabetes in Pima Indian type 2 diabetes families, also have evidence that supports the importance of maternal diabetes in determining the risk for diabetes in the offspring (443). In these studies, 45% of the offspring of women diabetic before pregnancy were themselves diabetic by age 20–24 years, compared with 1.4% and 8.6% of the offspring of nondiabetic and “prediabetic” women (women who became diabetic later), respectively. The paternal diabetic status appeared to contribute little additional risk to the offspring, after correcting for maternal diabetes and other risk factors (443). Significant excess maternal transmission of diabetes and an insulin-resistant phenotype characterized by heart disease, stroke, and hypertension, was also described in a Mexican-American type 2 diabetes population (444), although these findings were not observed in a similar population (445). Finally, Lin and coworkers (446) have described a maternal excess of diabetes inheritance in a Taiwanese population, with an odds ratio for reporting maternal diabetes of 2.64 (95% CI: 1.12–5.71) in diabetic patients compared with nondiabetic subjects.

Mitochondrial mutations could explain this excess maternal transmission. Indeed, inheritance of mitochondrial gene mutations leading to defects in glucose tolerance has been identified. The first mitochondrial mutation causing diabetes was shown to be caused by inheritance of deletions or duplications at a common breakpoint in the mitochondrial genome; however, this was shown in only one pedigree (447,448). A more widespread mutation at nucleotide 3243, a conserved position in the mitochondrial gene for tRNA Leu(UUR), has been reported by multiple groups in diabetes with maternal transmission history and associated hearing loss. This mutation alters the dihydrouridine loop in this tRNA, leading to impairment of mitochondrial transcription termination. This may cause defects in mitochondrial translation and protein synthesis. This same mutation is also responsible for the more dramatic MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) (448,449). Individuals with this mutation have been characterized as having insulin secretory defects along with an increased prevalence of sensorineural deafness or maternally inherited diabetes and deafness (MIDD) (450,451,452). Additionally, some of these individuals with the nucleotide 3243 mutation have been islet cell antibody positive type 2 diabetes patients who went on to require exogenous insulin therapy, due to beta-cell destruction and/or failure (453). The reason for the marked phenotypic variability seen in association with the 3243 mutation is still unclear. Although it has been proposed that the degree of heteroplasmy may explain the phenotypic variation, this appears to be an inadequate explanation. It is possible the mitochondrial–nuclear gene interactions are important (454). Like MODY, mitochondrial mutations are likely to account for only a small proportion of type 2 diabetes cases; Smith and colleagues (455) estimated that the 3243A–G mutation accounts for 0.5–2.8% of diabetes. Variants in nuclear-encoded mitochondrial genes also do not appear to play a significant role in typical type 2 diabetes (456). A number of other rare mutations in the mitochondrial genome have also been shown to cause diabetes, often but not always with associated hearing loss (457–460).

Several other hypotheses have been generated to explain this excess maternal transmission. These include: (1) a metabolic (teratogenic) effect of a diabetic or subclinical diabetic (“prediabetic”) environment during pregnancy; (2) the involvement of an imprinted gene that is only expressed when it is passed through a female meiosis; and (3) reporting bias. One of the GWAS-discovered loci for type 2 diabetes, KLF14, exhibits imprinted expression from the maternal allele, with maternal expression of the risk allele responsible for the effect on diabetes risk (413). Parent-of-origin effects have also been observed at the KCNQ1 locus (461). Reporting bias seems an unlikely explanation, however, as this phenomenon has also been observed in rats. Results from crosses between Goto-Kakizaki rats, which exhibit spontaneous type 2

diabetes, and outbred nondiabetic Wistar rats have demonstrated an effect of maternal inheritance on diabetes in offspring of the first generation (383). These hypotheses are not exclusive and one or more may be interacting to cause the observed excess maternal transmission of disease.

Several reports have identified low birthweight as a risk factor for type 2 diabetes and insulin resistance, suggesting a mechanism that may support maternal transmission (462–465). Decreased numbers of beta cells and impaired beta cell function have been associated with low birthweight, but a lack of correlation between low birthweight and the subsequent development of diabetes suggests that additional genetic or environmental factors are necessary for the development of type 2 diabetes (466). Furthermore, there were no differences in the birthweights of individuals with type 2 diabetes, impaired glucose tolerance, or normoglycemic subjects when the offspring of hyperglycemic and normoglycemic mothers were considered separately (466). Thus, these data do not provide conclusive evidence for a fuel-mediated teratogenic mechanism since diabetic mothers were no more likely than nondiabetic mothers to have babies of low birthweight.

Further research examining mitochondrial genes, sex-influenced autosomal loci, and environmental factors is warranted.

### 86.5.10 Genetic Counseling for Type 2 Diabetes

For the most part, we must depend on empirical recurrence risks for genetic counseling. For relatives of an individual with type 2 diabetes, the empirical recurrence risk to first-degree relatives is of the order of 10–15% for clinical diabetes and 20–30% for impaired glucose tolerance. In general, this increased risk appears to be for type 2 diabetes, not for type 1 diabetes, although as discussed previously, in some studies there is a somewhat increased risk for both forms of diabetes (467). For MODY diabetes, in whom diabetes is an autosomal dominant disorder, the risk to siblings and offspring is 50%.

**86.5.10.1 Screening and Prevention for Type 2 Diabetes.** Screening of first-degree relatives of type 2 diabetes can be accomplished by periodic glucose tolerance testing. In scenarios where this is not feasible, easily obtained clinical parameters can be entered into prediction tools to calculate the current (468) or future (469) risk of diabetes. Those relatives with impaired glucose tolerance should be advised to attain ideal body weight through diet and exercise, as this will improve glucose tolerance. This should be strongly encouraged, with the goals being to delay or prevent progression to frank diabetes and minimize the cardiovascular risks associated with impaired glucose intolerance. Indeed, lifestyle modification in subjects with impaired glucose tolerance has been demonstrated to reduce the incidence of type 2

diabetes by approximately 60% (470,471). Screening and intervention for other risk factors for cardiovascular disease (e.g. hypertension and hyperlipidemias) is also important, as a family history of diabetes is a significant risk factor for CAD.

Screening and implementation of appropriate life style modifications must begin early in life. While type 2 diabetes (with the exception of MODY) is traditionally thought of as an adult-onset disorder, there is a rapidly growing epidemic of adolescent and childhood onset of type 2 diabetes (472), particularly in children of Mexican American and African American descent (472,473). While the etiology is still under investigation, it appears that overeating and a sedentary lifestyle, in the context of a family history of type 2 diabetes, markedly increase risk.

Further refinement of genetic risk currently is only possible in MODY families and in those rare forms of type 2 diabetes due to mutant insulin, insulin receptor variants, or mitochondrial mutations. In such families, individuals at risk can potentially be identified at any age at which DNA can be obtained (e.g. even in childhood or prenatally). The issues that must be considered before going to DNA studies are complex, however. Particularly with forms of diabetes that have a later (e.g. adult) onset, the benefit of childhood carrier detection is not clear, and there is the risk of stigmatization as well as the risk of adversely impacting insurability. Therefore the pros and cons of DNA analysis should be discussed carefully before any testing. As discussed above, it is currently premature to utilize genes for typical type 2 diabetes as predictive tools, although private companies have already made this available to the public.

**86.5.10.2 Type 2 Diabetes and Pregnancy.** As detailed previously in the section discussing pregnancy and type 1 diabetes, it is well known that women with diabetes have a higher rate of pregnancy complications than do nondiabetics. Although attention is usually focused on the pregnant patient with type 1 diabetes, women with type 2 diabetes are also at increased risk for complications during pregnancy. In general, the more severe the diabetes, the poorer the pregnancy outcome. Women with type 2 diabetes have a significantly increased risk of delivering a child with congenital malformations (226,227,474,475), but the risk is probably less than that for women with type 1 diabetes. Becerra and coworkers (474) reported that the relative risk for major malformations for women with type 1 diabetes was 7.9 (95% CI: 1.9–33.5) as compared to nondiabetic women, whereas the relative risk for women with type 2 diabetes who required insulin treatment during pregnancy was 3.4 (95% CI: 1.0–11.7). Towner and colleagues (475) reported a major malformation frequency of 8.9% in women with type 2 diabetes. The spectrum of malformations was similar to that seen in association with type 1 diabetes. Of importance is that the risk of malformations was correlated with the degree of maternal glycemic control, suggesting

that preconceptional optimization of metabolic control is as important in women with type 2 diabetes as in those with type 1 diabetes.

With the trend toward delaying pregnancy into the 30s and 40s, coupled with the increasing proportion of the US population that is of Hispanic ethnic background, type 2 diabetes in pregnancy will be seen with increasing prevalence and may, without appropriate intervention, become an increasingly important cause of congenital anomalies (475,476). Women with type 2 diabetes should be counseled about the risks associated with diabetes in pregnancy and encouraged to maximize diabetes control before conception.

Prenatal diagnostic tests should also be recommended for all pregnant women who have type 2 diabetes, similar to those recommended for type 1 diabetes. These tests include ultrasonography to evaluate fetal growth and to rule out major fetal structural anomalies such as renal agenesis, neural tube defects, and caudal regression; fetal echocardiography (at 18–22 weeks' gestation) to identify major structural cardiac malformations; and MSAFP screening to screen for neural tube defects. Since there is evidence that in the general population folic acid supplementation begun before conception is helpful in decreasing the risk for neural tube defects (243–246), folic acid supplementation before conception should be strongly considered as the potential benefits (i.e. possibly reducing the risk for neural tube defects) outweigh any known risks.

## 86.6 FINAL CONSIDERATIONS AND SPECULATIONS

### 86.6.1 Evolutionary Aspects

Heterogeneity within both the insulin-dependent and non-insulin-dependent types of diabetes appears extensive. An important question arises from the population genetic viewpoint as to why these genes should be so prevalent. These diabetic disorders, whose susceptibility appears to be primarily genetically determined, are deleterious, and thus reproductive fitness should be impaired. As regards type 2 diabetes, a possible explanation is the concept of a “thrifty” genotype, as first proposed by Neel (477). He proposed that the diabetic genotype somehow allowed more efficient utilization of foodstuffs by the body in periods of famine to which primitive humans were often exposed. Such a thrifty gene would therefore have a selective survival advantage and would tend to increase in frequency. However, in the modern western world, with its continuous abundance of calories, such a gene would lead to diabetes and obesity. Neel's hypothesis has received support by observations in both humans and animals. The extremely high frequency of diabetes and obesity in populations such as the Pima Indians (478) and Pacific Islanders (479,480), and their apparent increase with modernization and urbanization, are

entirely consistent with the thrifty genotype hypothesis. Direct support comes from studies that have shown that heterozygotes for rodent diabetes–obesity genes exhibit a much better ability to survive fasting than normal rodents (480).

What might be the selective advantage of the genes that predispose to type 1 diabetes? Since type 1 diabetes is a disorder in which autoimmunity and immune response genes are implicated, a possible role in the resistance to infectious agents has been proposed. However, one should realize that the problem of the selective advantage of type 1 diabetes is much greater than for type 2 diabetes. Before the onset of insulin therapy, type 1 diabetes was usually a lethal disorder, at least in genetic terms (i.e. failure to reproduce). Since susceptibility seems to be provided even by single alleles of HLA-linked genes, this negative selection is much greater than that for recessive genetic disorders such as sickle cell anemia or Tay-Sachs disease, where negative selection operates only on those homozygous for the disease genes. Thus, one would suppose that the positive selective advantage would of necessity be dramatic and that the positive selection should have continued into modern human history. Otherwise the incidence of the disorder would have been decreasing dramatically before the advent of insulin therapy. Yet no such positive selective advantage has been discerned, at least postnatally. Evidence has been developed that indeed suggests a potential selective advantage mechanism for type 1 diabetes in utero. What has been observed in some studies is preferential transmission of diabetogenic HLA haplotypes, not only to affected offspring but also to unaffected offspring (481,482). Furthermore, the available evidence suggests that this possibly occurs via in utero selection (482,483). These data may thus provide an explanation for the maintenance of the high population frequency for this previously frequent genetically lethal disease. In addition, the suggestion that this prenatal selection could occur via immunologically mediated events raises the theoretical possibility that an additional consequence of these events, in fetuses that survive, might be immune changes that presage the eventual development of type 1 diabetes (270,484).

### 86.6.2 Counseling Summary

Given these recent advances in our knowledge of the genetics and heterogeneity of diabetes, what is the genetic counseling we can provide at this time to our diabetic patients? First, as in all genetic counseling, an accurate diagnosis must be made. On clinical grounds one can distinguish between type 1 typically juvenile-onset insulin-dependent type diabetes, type 2 maturity-onset non-insulin-dependent type diabetes, and MODY type diabetes. In distinguishing among these phenotypes, one already has important counseling information. As discussed previously, in a given family the increased risk for

diabetes over the general population is in general only for the specific type of diabetes that has already occurred in the family, not for all diabetes. Thus, if the index case presenting for counseling is a juvenile insulin-dependent diabetic, the increased risk for that patient's relatives is for type 1 diabetes. If the index case is a non-insulin-dependent diabetic, the increased risk for the patient's relatives is, for the most part, for type 2 diabetes only. Associated abnormalities or diseases may suggest one of the rare genetic syndromes that include diabetes, where the risk of recurrence is dependent on the specific diagnosis.

Once we have accurately characterized the clinical phenotype of the patient, how do we then proceed? At this stage, we must fall back for the most part on observed empirical recurrence risks (i.e. data concerning the actually observed recurrence of these disorders in a large number of families). Even these empirical recurrence risks have limitations, since for the most part they have been reported only from white populations. Even with the reservation that these empirical risks can be safely applied only to the populations from which they were derived, the most reassuring aspect of the data is the overall low absolute risk for the development of clinical diabetes in first-degree relatives, especially for insulin-dependent diabetes.

The heterogeneity that has so far been discovered among typical diabetes mellitus probably represents just the tip of the iceberg. But even this currently demonstrable heterogeneity has immediate relevance to current research efforts into the pathogenesis and therapy of the diabetic state. The susceptibility to a given environmental agent may very well depend on the heterogeneity elucidated by these studies. There may also be heterogeneity in the diabetic complications associated with genetically distinct forms of diabetes, having implications for disease management. Only when each of the many disorders resulting in diabetes mellitus and/or glucose intolerance are delineated will specific prognostication and therapy be possible for all diabetic patients.

### 87.1 CLINICAL ASPECTS: NORMAL AND ABNORMAL ADRENAL FUNCTION

#### 87.1.1 Endocrine Functions of the Adrenal Cortex

The adrenal cortex produces numerous steroids, secreted in widely varying amounts, each of which has a different potency of hormonal action (Figure 87-1). According to their primary effect, these are classified as mineralocorticoids (MCs), glucocorticoids (GCs), or sex steroids.

Aldosterone is the end product of the MC pathway. It is the most potent steroid affecting active transport of sodium ions across membranes and thus in maintaining electrolyte balance. The primary site of action of aldosterone is at the renal distal convoluted tubules and the cortical collecting ducts, where it promotes reabsorption of the crucial 2% of sodium to be regained from the renal filtrate.

Cortisol, the principal GC in humans and most mammalian primates (1) is quantitatively the main secretory product of the adrenal cortex. It is indispensable for proper carbohydrate metabolism and in ensuring systemic capacity to withstand events of stress such as infection and trauma. Several studies have defined important mediating roles for GCs in the functioning of the immune response (2–5).

The major sex steroids secreted by the adrenal cortex are dehydroepiandrosterone (DHEA) and its sulfate; androgenic steroids and estrogens are normally very minor products. In late childhood, there is a significant rise in adrenal

sex steroid production, termed the adrenarche, leading to further complex interactions with the hypothalamus–pituitary axis and the gonads in preparation for puberty and the transition to sexual maturity (6). This remains the least understood aspect of the function of the adrenal cortex.

#### 87.1.2 Regulation of Steroid Synthesis

The adrenal cortex is divided histologically into three regions: the outer zona glomerulosa, the wide middle zona fasciculata, and the more compact inner zona reticularis adjoining the adrenal medulla. Differences in the production of MCs, GCs, and sex steroids by the adrenal cortex are determined by local activities of certain adrenal enzymes, which correspond in large part with this zonation (7). Synthesis of the MC aldosterone is dependent on enzymatic activity limited to the zona glomerulosa, while production of cortisol and androgens requires enzymes found in the middle and inner zones, the zona fasciculata and zona reticularis. Adrenal steroid synthesis depends predominately on the tropic effects of the anterior pituitary peptide, adrenocorticotrophic hormone (ACTH). ACTH exercises acute and chronic effects on adrenocortical cell processes (8), resulting in an acute response that produces up to 10-fold amplification of the rate of steroidogenesis within 2–6 min. Corticotropin releasing hormone (CRH), produced in the hypothalamus, and vasopressin located in the posterior pituitary synergistically stimulate ACTH production (9–12). The

**FIGURE 87-1** Schema of adrenal steroidogenesis. (From New, M., White, P. In: Genetic and Molecular Biological Aspects of Endocrine Disease; Balliere Tindall: London, 1995, pp: 526.)

most direct result of the intracellular changes induced by ACTH in the adrenal cortex is the increased availability of cholesterol as substrate to cholesterol desmolase, the first enzyme in steroid synthesis. The rate-limiting step in steroidogenesis is cholesterol transport to the matrix side of the inner mitochondrial membrane, which is regulated by the steroidogenic acute regulatory protein (StAR). StAR acts by increasing the flow of cholesterol into the mitochondria. StAR acts on the outer mitochondrial membrane to promote sterol translocation to P450<sub>scc</sub>, and the importation of StAR into mitochondria terminates its action (13). Cholesterol for steroid biosynthesis is provided by the cytoplasmic pool of free cholesterol, which is supplied primarily by the action of cholesteryl ester hydrolase. This kinase-dependent enzyme hydrolyzes cholesterol from cholesteryl esters in cytoplasmic lipid droplet stores.

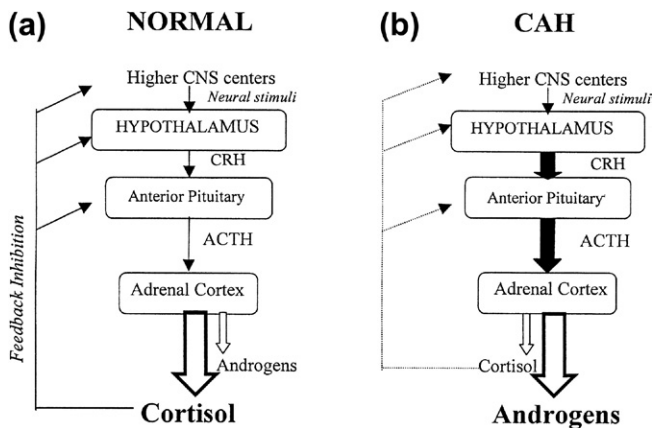

Continued adrenal steroid demand depletes this intracellular source, at which stage uptake of plasma low-density lipoprotein (LDL) provides further quantities of cholesterol and, after prolonged stimulation, cholesterol biosynthesis within the cell becomes significant.

Continued elevation of ACTH also produces progressively wider effects within the cell, increasing mRNA transcription and protein translation rates for each of the enzymes in the cortisol synthetic pathway (14), the enzymes governing lipoprotein endocytosis and

intracellular movement of cholesterol (with up-regulation of the cell surface lipoprotein receptor), and, given sufficiently prolonged stimulation, eventually for the enzymes of cholesterol synthesis as well (8,15).

### 87.1.3 Cortisol and Adrenocorticotrophic Hormone

The synthesis of cortisol is modulated directly by the net circulating levels of ACTH. ACTH, a peptide with a relatively short plasma half-life, is one of a group of trophic hormones cleaved from a high-molecular-weight precursor, proopiomelanocortin. ACTH is stored in the corticotroph cells of the anterior pituitary. Pulsatile release of ACTH from this cell population is in turn modulated by CRH. The hypothalamic–pituitary–adrenal axis forms a regulated system (Figure 87-2). Negative feedback control is exerted by cortisol, and the central nervous system (CNS) determines the hypothalamic setpoint for the expected plasma cortisol level. Net ACTH release has basal, diurnal, and stress-induced components. Plasma cortisol levels lower than the hypothalamic–pituitary setpoint will increase the rate and intensity of ACTH secretory pulses. Adrenal enzyme deficiencies causing impaired synthesis and decreased secretion of cortisol thus lead to chronic elevations of ACTH with overstimulation and consequent hyperplasia of the adrenal cortex.

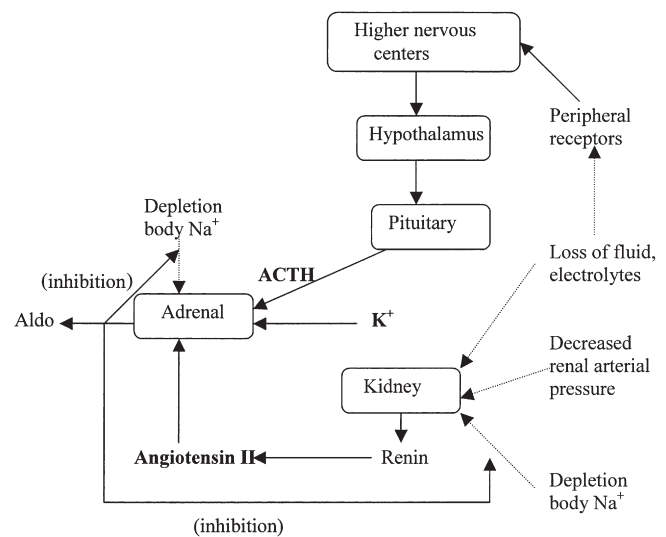

**FIGURE 87-2** Feedback in the hypothalamic-pituitary-adrenal axis in (a) the normal individual and in (b) the patient with classic congenital adrenal hyperplasia.

### 87.1.4 Aldosterone and Renin-Angiotensin

The primary regulation of aldosterone synthesis is via the renin-angiotensin system (RAS) (16), which is responsive to the state of electrolyte balance and plasma volume. The enzyme renin, which arises from the renal juxtaglomerular apparatus, cleaves the decapeptide angiotensin I from angiotensinogen, a plasma  $\alpha_2$ -globulin. Angiotensin I is then further converted enzymatically by passage through the lungs to the octapeptide angiotensin II. Angiotensin II is a potent vasoconstrictor that directly stimulates aldosterone secretion by the zona glomerulosa (17). Aldosterone secretion is also stimulated directly by high serum  $K^+$  concentration, less sensitively by low serum  $Na^+$  concentration, and by ACTH (17). ACTH has a permissive role through its general effect on adrenocortical function but, in addition to this, the zona glomerulosa is transiently very sensitive to ACTH, especially when the late aldosterone synthetic stages specific to this zone have been potentiated by chronic angiotensin II stimulation or electrolyte imbalance ( $K^+$  loading/ $Na^+$  restriction) (18). In addition, cis-regulatory elements appear to influence transcription of aldosterone synthase (CYP11B2), the enzyme that catalyzes the final steps in aldosterone synthesis, but further studies will be necessary to define these factors (19). Thus, the four major factors affecting aldosterone synthesis by the zona glomerulosa are angiotensin II,  $K^+$ ,  $Na^+$ , and ACTH (Figure 87-3).

### 87.1.5 The Adrenal Cortex as Two Glands

Proper adrenal development in the fetus is essential for fetal maturation and survival in the perinatal period (20). While the adrenal medulla cells originate in the neuroderm, primitive cells of the adrenal cortex are first identified in the fourth week of gestation arising from the mesoderm. In the following weeks, the migrating cells organize into two separate zones: the fetal zone and the definitive (adult) zone (21). The fetal zone is much larger

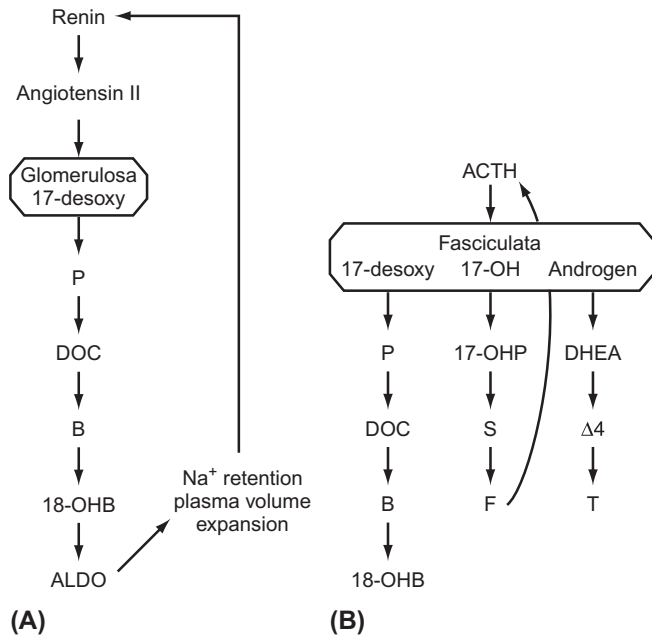

**FIGURE 87-3** Regulation of aldosterone production by the four major factors: angiotensin II, plasma potassium ion ( $K^+$ ), ACTH (adrenocorticotropin), and sodium ( $Na^+$ ). (From New, M. I.; Peterson, R. E. *Disorders of Aldosterone Secretion in Childhood*. *Pediatr. Clin. North Am.* 1966, 13, 43–58.)

than the very compact definitive zone and is responsible for the majority of fetal steroidogenesis, including DHEA sulfate. ACTH is the primary trophic regulator of the fetal adrenal cortex; however, growth, transcription, and placental factors are also important in development of the cortex. Remodeling of the adrenal cortex occurs in the neonatal period when the fetal zone atrophies and the three zones of the adult cortex develop (22).

The zonal theory of the adrenal cortex indicates that the zona glomerulosa and the zona fasciculata are histologically distinct cell populations. New and Seaman (23) formulated the idea that the adrenal behaves hormonally and biochemically as two separate glands with respect to regulation and secretion. Steroidogenesis in the fasciculata is regulated primarily by ACTH (in the hypothalamic-pituitary-adrenal axis), the ACTH stimulating secretion of cortisol, deoxycorticosterone (DOC), corticosterone, and androgens. Steroidogenesis in the glomerulosa is regulated primarily by angiotensin II (in the RAS) and potassium; angiotensin stimulating aldosterone secretion through ACTH presumably exerts only a secondary influence in this zone (Figure 87-4). The zona fasciculata does not exhibit the enzymatic activity necessary for the terminal step of aldosterone synthesis, whereas the zona glomerulosa lacks the  $17\alpha$ -hydroxylase activity required for the production of  $17$ -hydroxycorticoids and androgens.

### 87.1.6 Adrenal Steroids in Development

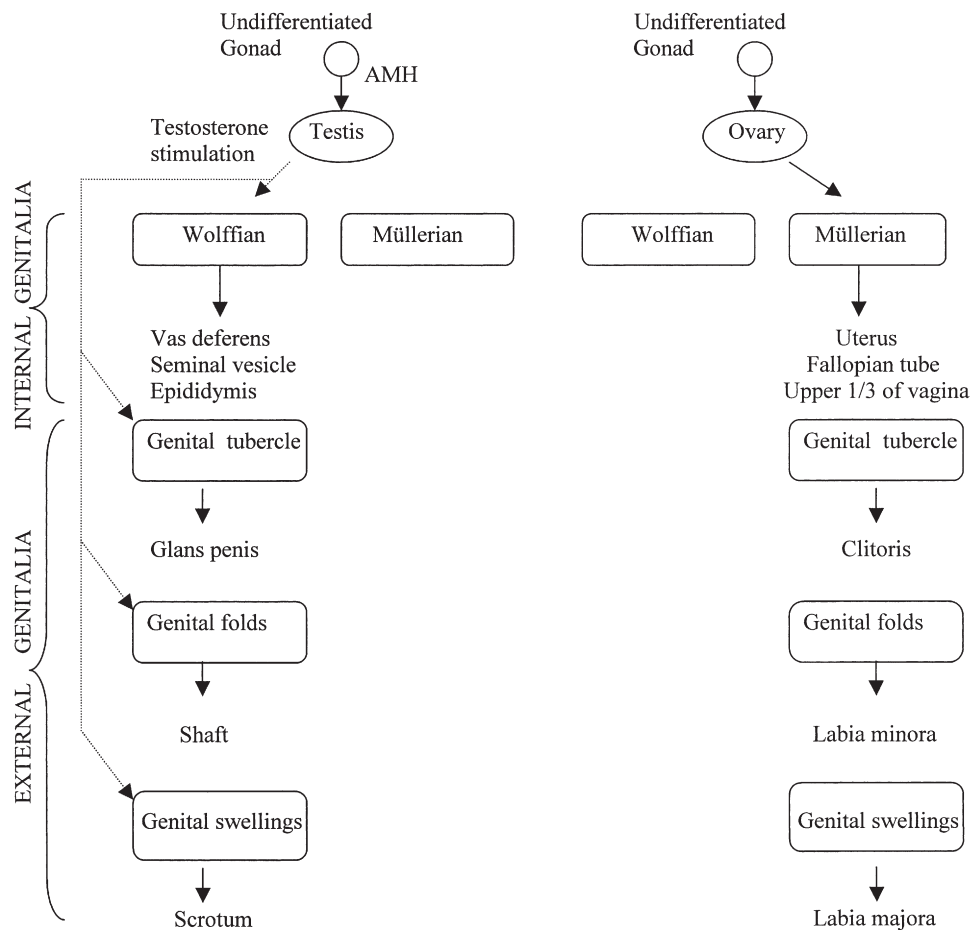

Normal male genital differentiation in embryonic and fetal life is dependent on two functions of the fetal testes (24): (1) the secretion of sufficient quantities of testosterone to direct the formation of the internal male genital structures (i.e. the epididymis, vas deferens, seminal vesicles, and

**FIGURE 87-4** Regulation of adrenocortical steroid production considering (a) the zona glomerulosa (ZG) and (b) the zona fasciculata (ZF) as two separate glands in two separate negative (inhibitory) feedback loops. (From Reference (69).)

ejaculatory ducts) from the Wolffian (mesonephric) ducts and (2) the secretion of a nonsteroidal factor to suppress development of the müllerian ducts into the female internal structures (i.e. the fallopian tubes, uterus, cervix, and upper vagina) (Figure 87-5). This factor, anti-müllerian hormone (AMH), also termed müllerian inhibiting substance (MIS) or factor (MIF), is a glycoprotein dimer (25) known to belong to a superfamily of peptide growth/differentiation factors, including the activins and transforming growth factor- $\beta$  (TGF- $\beta$ ) (26). In the fetal testis, AMH is first synthesized by differentiating Sertoli cells (27) at 6–7 weeks of gestation and thus precedes testosterone secretion by the Leydig cells, which begins at about the eighth week. Since there is no anomalous production of AMH in the gonadally normal female, females suffering even the most extreme virilization from adrenal androgen excess have normal development of the internal genital structures. The rescue of childbearing capacity in these gonadally intact patients is thus a prime goal of treatment in congenital adrenal hyperplasia (CAH).

Testosterone is also required for suppression of the breast anlage and indirectly for normal formation of the male external genitalia. To act on the tissues of the external genital primordium, testosterone must first undergo peripheral conversion to dihydrotestosterone (DHT). The

**FIGURE 87-5** Fetal sex differentiation. (From Reference (167).)

differentiation promoted by DHT includes formation of the scrotum from the genital swellings, midline closure of the genital folds, elongation into the body of the phallus, and extension of the urogenital sinus by fusion along the ventral groove to form a penile urethra (28).

Pertaining to the virilizing forms of CAH, progressive differentiation toward the male type in genetic females has been given a five-stage classification by Prader (29,30). Raised androgen levels from abnormal fetal adrenal function (virilizing adrenal hyperplasia) or from the mother (an androgen-producing tumor or exogenous androgen administration during pregnancy) do not affect genital development in the male fetus because of the already high levels of androgens produced by the testes. The androgen levels, however, are high enough to cause significant masculinization of the external genitalia in females. Virilized genitalia of the female fetus have now been reported to also result from changes in steroid conversion consequent to a defect in the placental aromatase enzyme (31,32). To date, there have been seven males and seven females reported with aromatase deficiency (33). In pregnancies at risk of a female child affected with virilizing adrenal hyperplasia, successful suppression of fetal adrenal androgen production has resulted by giving the mother GCs able to cross the placental barrier (see discussion of CAH prenatal diagnosis and treatment, in Section 87.8).

### 87.1.7 Pathogenesis of Congenital Adrenal Hyperplasia

CAH refers to the histological alterations consequent to elevated ACTH and chronic glandular overactivity resulting from the inability of the adrenal cortex to achieve normal plasma cortisol levels in response to (normal) ACTH stimulation (see Figure 87-2). With the exception of lipoid CAH, CAH arises biochemically from reduced or absent enzymatic activity at one of the steps of steroid synthesis. Each deficient enzymatic step produces characteristically abnormal adrenal hormone and precursor levels. The varying patterns of imbalance give rise to a wide range of clinical effects manifesting in metabolic disturbances and developmental abnormalities.

The following enzymatic defects of steroidogenesis and their associated clinical syndromes have been described (34–37):

1. 21-Hydroxylase deficiency (classic salt wasting, classic simple virilizing, and nonclassic)
2. 11 $\beta$ -Hydroxylase deficiency (classic and nonclassic)
3. 3 $\beta$ -Hydroxysteroid dehydrogenase (3 $\beta$ -HSD) deficiency (classic and nonclassic)
4. 17 $\alpha$ -Hydroxylase/17,20-lyase deficiency
5. Congenital lipoid adrenal hyperplasia (StAR deficiency)

The 21- and 11 $\beta$ -hydroxylase deficiencies, occurring distal to the common precursor stages, cause channeling of these precursor steroids into the androgen pathway,

resulting in virilization of females and hyperandrogenic effects in both sexes. In the 3 $\beta$ -HSD defect, there is glandular production only of  $\Delta^5$  steroids, which are relatively inactive. While lack of testicular production of  $\Delta^4$  androgens produces pseudovaginal hypospadias in the male, enormously high-secreted levels of DHEA may undergo peripheral conversion to more potent androgens, which are then able to cause external virilization in females. In 17 $\alpha$ -hydroxylase deficiency, there is extremely high production of 17-deoxysteroids: corticosterone (B), which has some GC function, and 11-deoxycorticosterone (DOC), which causes hypertension. Blocked formation of C<sub>19</sub>/C<sub>18</sub> steroids in both the 17 $\alpha$ -hydroxylase/17,20-lyase deficiency and the isolated 17,20-lyase defect (in which cortisol production is intact) causes undervirilization in males and sexual infantilism in females. Congenital lipoid adrenal hyperplasia results from a complete inability to synthesize steroids causing lipid accumulation in adrenal cells, and along with the very serious effects of adrenal insufficiency, undervirilization occurs in genetic males.

### 87.1.8 Classic and Nonclassic Forms

Total or near-total blocks in the activity of these enzymes result in genital ambiguity and represent the classic form of CAH (36). Improved biochemical assessment of adrenal function now allows for the identification of lesser enzyme defects also, which cause milder endocrine disturbance and absence of genital ambiguity. Called nonclassic forms, such partial defects have been confirmed for steroid 21-hydroxylase (38), steroid 11 $\beta$ -hydroxylase (39), and 3 $\beta$ -HSD (40). As might be expected, nonclassic defects are much more common than occurrences of the corresponding classic defects.

## 87.2 STEROID 21-HYDROXYLASE DEFICIENCY

Decreased cortisol synthesis owing to impaired steroid 21-hydroxylation is the most common biochemical cause of CAH. The decreased plasma cortisol induces pituitary ACTH secretion, stimulating the adrenal cortex and causing elevated adrenal production both of cortisol precursors and of androgens that do not require 21-hydroxylase for their biosynthesis. Early clinical studies showed increased amounts of pregnanetriol, the principal metabolite of 17 $\alpha$ -hydroxyprogesterone (17-OHP), 17-ketosteroids (17-KS; 17-oxosteroids), resulting from the metabolism of DHEA,  $\Delta^4$ -androstenedione ( $\Delta^4$ -A), and testosterone, present in the urine of patients with 21-hydroxylase deficiency. Radioimmunoassay (RIA)-based laboratory procedures for the determination of hormone levels in serum are simple, reliable, and allow for a more accurate diagnosis than could be provided formerly by methods assessing urinary hormone and metabolite levels.

### 87.2.1 Classic 21-Hydroxylase Deficiency

**87.2.1.1 Simple Virilizing Form.** The prominent feature of 21-hydroxylase deficiency is progressive virilization with advanced somatic development. The classic disorder is of the simple virilizing type in about one-fourth to one-third of cases. Developmental genital anomalies manifest in females as varying degrees of genital ambiguity, which should flag the diagnosis in the female. Because genital formation in males is normal, before the wide implementation of the newborn screening program for CAH, the disease often went unrecognized until signs of androgen excess such as accelerated height and precocious sexual hair appeared later in childhood.

Adrenocortical cell differentiation and the formation of the fetal zone occur early in embryogenesis, and it is clear that genital development in the fetus takes place under the influence of active adrenal steroid synthesis. Thus, in the female, the extent of masculinization of the external genitalia ranges from mild clitoral enlargement, through varying degrees of fusion of the labioscrotal folds (posterior to anterior), to the profound morphological anomaly of a penile urethra.

Genetic sex, gonadal differentiation, and internal genital morphogenesis are normal in 21-hydroxylase deficiency. Since there is no anomalous secretion of AMH in the female, the müllerian ducts develop normally into uterus and fallopian tubes. Wolffian duct stabilization and differentiation proceed under the control of high intraluminal levels of gonadal androgens in the male; this process appears to be unaffected by elevated adrenal androgens, and there is no observable Wolffian development in females with 21-hydroxylase deficiency CAH.

The most common cause of ambiguous genitalia in the newborn female is 21-hydroxylase deficiency, and because affected females have the capacity for an entirely normal female sex role including childbearing, it is very important to recognize this disorder in newborns. Although the male is not jeopardized by inappropriate sex assignment, premature masculinization, short stature, and accelerated physical development cause problems of social and physical adjustment. In addition, continued adrenal androgen excess may suppress the pituitary–gonadal axis, preventing maturation of the testes, resulting in infertility (41,42). In both sexes, there is early fusion of the epiphyses, causing short adult stature.

**87.2.1.2 Salt-Wasting Form.** Two-thirds to three-fourths of classic cases (i.e. presenting at birth) of 21-hydroxylase deficiency present with renal salt wasting, primarily from deficient aldosterone synthesis (43), defined by hyponatremia and hyperkalemia, inappropriately high urinary sodium, and low serum and urinary aldosterone with concomitantly high plasma renin activity (PRA). The increase in the proportion of salt wasting cases in recent years can be attributed to better case identification and patient survival. In addition to inadequate secretion of aldosterone or other

salt-retaining steroids, other precursors with natriuretic action produced in excess may counter the marginally competent sodium-conserving mechanism of the immature newborn renal tubule (44–46). Salt loss in infancy from an aldosterone biosynthetic defect may improve with age (39,47,48), and possible adjustments in sodium intake and MC replacement in patients labeled neonatally as salt wasters can be made on the basis of careful monitoring of PRA.

Although correlation of the severity of salt wasting with the extent of virilization has been claimed (49), the degree of genital ambiguity in a female newborn does not indicate the form. Even mildly virilized newborn females with 21-hydroxylase deficiency may be salt wasters and should be observed carefully for signs of adrenal insufficiency in the first weeks of life.

With a few exceptions (48,50,51), the presence or absence of salt wasting in 21-hydroxylase deficiency has been seen consistently within families, and subsequent affected offspring have thus been expected to have the same form of the disease as the index case. However, discordance for salt wasting has been found in several families among siblings whose molecular studies confirmed identical mutations (52–54).

**87.2.1.3 Nonclassic 21-Hydroxylase Deficiency.** An attenuated, late-onset form of adrenal hyperplasia was first suspected during the early 1950s by gynecologists in clinical practice who used GCs on an empirical basis to treat women with physical signs of hyperandrogenism, including infertility. The first biochemical documentation of an apparent 21-hydroxylase defect was by Baulieu and coworkers in 1957 (55). During the next two decades, glucocorticoid treatment of virilized women became commonplace, and in cases of a good response it was assumed that the androgens were of adrenal origin.

Diagnosis of 21-hydroxylase defects on the basis of serum steroid measurements became feasible with the development of a specific RIA for 17-OHP (56), the steroid immediately proximal to the adrenal 21-hydroxylating step in the cortisol pathway, and thus the index compound for the 21-hydroxylase defect. Based on RIA assays, family members of CAH patients were found to have serum elevations of 17-OHP above the intermediate levels observed for most heterozygotes for a severe 21-hydroxylase-deficiency gene (57). Many family studies on classic 21-hydroxylase deficiency followed the initial report by Dupont and coworkers (58) of genetic linkage of CAH (21-hydroxylase deficiency) with human leukocyte antigen (HLA). Through such studies, the existence of nonclassic 21-hydroxylase deficiency alleles became apparent (59–62). Linkage of nonclassic 21-hydroxylase deficiency to HLA was established (63,64), confirming that this disorder was allelic with the classic defect (59,65). It is now known that mutations in the gene for 21-hydroxylase associated with the nonclassic defect are distinct from those found in the classic forms and often differ by ethnicity (54,66).

Clinical symptomatology of nonclassic 21-hydroxylase deficiency is variable and may present at any age. Nonclassic 21-hydroxylase deficiency can result in premature development of pubic hair in children; to our knowledge, the youngest such patient was noted to have pubic hair at 6 months of age (67). In a review of 23 cases presenting to The New York Presbyterian Hospital–Weill Medical College of Cornell University for evaluation of premature pubarche, seven children demonstrated a 17-OHP response to ACTH stimulation consistent with the diagnosis of nonclassic 21-hydroxylase deficiency, a prevalence of 30% in this preselected group of pediatric patients at high risk (68). Other investigators found four of 48 children with premature adrenarche to be affected with nonclassic 21-hydroxylase deficiency, demonstrating an ACTH-stimulated 17-OHP response greater than that of obligate heterozygote carriers of the 21-hydroxylase-deficiency gene (69,70). Elevated adrenal androgens promote the early fusion of epiphyseal growth plates; children with this disorder commonly have advanced bone age (67) and accelerated linear growth velocity (71), although they are ultimately shorter than the final height prediction based on mid-parental height and on linear growth percentiles before the apparent onset of excess androgen secretion.

Severe cystic acne refractory to oral antibiotics and retinoic acid has been attributed to nonclassic 21-hydroxylase deficiency (72,73). In one study comparing the responses of 11 female patients with acne and 8 (female) control subjects to a 24-h infusion of ACTH, elevated urinary excretion of pregnanetriol suggestive of a partial 21-hydroxylase deficiency was found in six patients (74). In another study of 31 young female patients with acne and/or hirsutism tested with low-dose ACTH stimulation after overnight dexamethasone suppression, no case of 21-hydroxylase deficiency was found (75). Male-pattern baldness has been noted in other cases as the sole presenting symptom in young women with nonclassic 21-hydroxylase deficiency.

Menarche in females may be normal or delayed, and secondary amenorrhea is a frequent occurrence (62,67). A sector of female nonclassic 21-hydroxylase deficiency patients represent a subgroup of women affected with polycystic ovarian disease (76–78). Initial-phase adrenal sex-steroid excess, disrupting the usual cyclicity of gonadotropin release and/or with direct effects on the ovary, is probable in the pathophysiology of this syndrome, ultimately leading to the formation of ovarian cysts, which then may continue autonomously to produce androgens.

Retrospective analysis identified partial 21-hydroxylase defects in 16 of 108 women (14%) presenting to New York Presbyterian Hospital–Weill Medical College of Cornell University for evaluation of hirsutism and oligomenorrhea (79). The prevalence of nonclassic 21-hydroxylase deficiency as an etiology of these endocrine complaints in women in other published series

ranges from 1.2% to 30% (76–78,80–82). The wide range of frequencies in these reports may relate to differences in the ethnic makeup of the groups studied since the disease frequency is ethnic specific.

Although the androgen profiles in serum and urine in either the basal or the ACTH-stimulated state may not be markedly different overall from those demonstrated by women with the syndrome of polycystic ovaries from other causes, the serum 17-OHP response on ACTH stimulation clearly differentiates the patients with an adrenal 21-hydroxylase defect (69,79). In one report, of six women with nonclassic 21-hydroxylase deficiency who underwent sonography or laparoscopic visualization of the ovaries, four had polycystic ovaries (69). Thus, even sonograms of the ovary do not distinguish women with excess androgens due to polycystic ovarian disease from those with nonclassic 21-hydroxylase deficiency. The response of the hypothalamic–pituitary–gonadal axis to luteinizing hormone-releasing hormone (LHRH) has been observed to be variably abnormal in virilized women with nonclassic 21-hydroxylase deficiency (83). An ACTH stimulation test is necessary to differentiate polycystic ovarian disease from nonclassic 21-hydroxylase deficiency after LHRH testing of pituitary gonadotropin secretion.

In boys, early beard growth, acne, and growth spurt may be detected. In cases of pubic hair growth and enlarged phallus from an androgen excess condition in boys, a reliable indication of an adrenal (as opposed to testicular) source of androgens is the proportionately small size of the testes that results from suppression of the hypothalamic–pituitary–gonadal axis. In men, signs of androgen excess are difficult to appreciate; the manifestations of adrenal androgen excess may be limited to short stature or oligozoospermia and diminished fertility from this same adrenal sex-steroid induced gonadal suppression reversible with GC treatment (41,42,84,85). Certain individuals—males and females—affected with nonclassic 21-hydroxylase deficiency have no overt symptoms of disease while demonstrating biochemical abnormalities comparable with patients. Longitudinal follow-up evaluation of these cases (usually detected as part of a family study) often shows signs of hyperandrogenism to wax and wane with time.

## 87.2.2 Epidemiology

**87.2.2.1 Classic 21-Hydroxylase Deficiency.** From the first separation of the “adrenogenital syndrome” into different enzyme defects, steroid 21-hydroxylase deficiency has been recognized to be the predominant form. It accounts for 90–95% of all cases of CAH. The incidence of classic 21-hydroxylase deficiency reported in numerous studies based on case presentation shows considerable variation. Currently, the combined figures from the largest newborn screening programs in different populations show an overall worldwide frequency of

1 per 13,000–15,000 live births (86), NNSIS 2009 National Newborn Screening Information System. (Available at <http://www2.uthscsa.edu/nnsis>).

In North America, the estimated incidence of virilizing CAH in the earliest regional (Maryland) study, which in fact was the first to establish that the disease shows autosomal recessive transmission, was very low, clearly due to incomplete case identification (the underrepresentation of males was recognized) (87). Subsequent regional studies by case presentation reported confirmed figures of 1 per 15,000, although suggested closer to one per 10,000 in one study (50) and one per 26,292 specifically for the salt-wasting form in another (88). Retrospective analysis of CAH births in the province of Manitoba for the period 1968–1988 revealed an incidence of 1 per 14,500 (similar to screening studies) but a skewed female/male sex ratio of 2.2:1, suggesting probable deaths of undiagnosed males (89). Newborn screening was operational in eight states (AK, GA, IL, IA, MA, NC, TX, WA) in the United States for the calendar year 1990, and the statistics from these programs gave a combined incidence of one in 16,116 (90). A recent report on the screening results of 1.9 million Texas newborns revealed an incidence of 1 in 16,008, with a ratio of salt wasting to simple virilizing of 2.7:1 (91). Currently all 50 states are participating in newborn screening for CAH.

European case survey studies have given regional incidences ranging from one in 13,000 to one in 23,040 in France (92,93), one in 21,000 in the Republic of Ireland

(94), one in 20,900 in Scotland (95), one in 18,500 and one in 15,500 in Switzerland (29,96), one in 12,100 in Wales (97), and one in 8990 in the Tyrol (98). The incidences reported from a few metropolitan area studies suggest better case identification: one in 9800 from Munich (99) and one in 5040 from Zurich (100). Combined data from more recent and ongoing neonatal screening programs in France show a sex ratio (M/F, 1:1.3) representing a deficit in the number of male patients detected (101). Incidences currently given by screening programs in some European and other countries are shown in Figure 87-6.

An initial case survey study in Japan had once suggested a somewhat lower incidence than in white populations, one in 43,674 (102). Nationwide screening in Japan has now determined that the incidence overall does not differ significantly from that in other countries (see Figure 87-6), and in fact for two of 11 regions an incidence significantly higher than in other areas was found (103).

Two isolates show unusually high incidences: Yup'ik Eskimo (Inuit) people of the Kuskokwim river delta in southwestern Alaska and the mixed colonial/indigenous population of the island of La Réunion in the Indian Ocean. On La Réunion, frequency observed by screening was one in 2220 in 1988 and one in 3540 cumulatively over a more than 10-year period (104). The high frequency of severe salt-wasting CAH among the Yup'ik (105,106) appears to result from a single mutation established in this group (107).

**FIGURE 87-6** Incidence of classic 21-hydroxylase deficiency as given by some current screening programs internationally. (Data from (86); Balsamo, A.; Cacciari, E.; Piazzzi, S.; et al. Congenital Adrenal Hyperplasia: Neonatal Mass Screening Compared with Clinical Diagnosis Only in the Emilia-Romagna Region of Italy 1980–1995. *Pediatrics* 1996, 98, 362–367.)

**87.2.2.2 Nonclassic 21-Hydroxylase Deficiency.** The high frequency of nonclassic 21-hydroxylase deficiency was first determined in a numerical analysis of genetic and hormonal data on a collection of pedigrees from a number of ethnic groups (108), and it was confirmed by a follow-up study using a more rigorous computer-based analysis by the method of commingling distributions (109). The gene frequency for nonclassic 21-hydroxylase deficiency was highest in Ashkenazi Jews and was also high in Hispanics, Yugoslavs, and Italians. Disease frequencies were 0.037 (one in 27) for Ashkenazi Jews, 0.019 (one in 53) for Hispanics, 0.016 (one in 63) for Yugoslavs, 0.003 (one in 333) for Italians, and 0.001 (1/1000) for other whites (Figure 87-7).

### 87.2.3 Molecular Genetics and 21-Hydroxylase Deficiency

The adrenal steroid 21-hydroxylase enzyme is a microsomal cytochrome P450. The members of this functionally diverse group of heme proteins are grouped into a number of families that all accept electrons from a NADPH-dependent cytochrome P450 reductase (110,111). The adrenal 21-hydroxylase is the unique known occupant of its family, XXI. Following the cytochrome P450

nomenclature, the enzyme and the gene encoding the enzyme are termed *CYP21A2*. This gene *CYP21A1P* is situated within the human major histocompatibility complex, HLA, on the short arm of chromosome 6, in a region exhibiting the highest gene density of all known chromosome regions to date.

The *CYP21A2* gene is mapped to 6p in a tandem paired arrangement with several other genes—two related active genes, *C4A* and *C4B*, the genes for the two isoforms of component C4 of serum complement; and a homolog to the *CYP21A2* gene, *CYP21A1P*, a pseudogene that retains 96–98% similarity in base sequence, but contains deleterious mutations generating a nonfunctional protein product. Flanking *C4A* and *C4B* in the 5' region are genes *RP1*, encoding a nuclear protein, and *RP2*, a pseudogene of *RP1*. On the opposite strand, extracellular matrix protein tenascin *TNXB* and *TNXA* overlap with the last exon of *CYP21A2* and *CYP21A1P* (112). The *C4* genes are both moderately allelic, expressing a number of serum variants (allotypes) for each isoform, which show fine differences in electrophoretic mobility, while generally the two *C4* isoforms (corresponding to the Rogers and Chido antigens) differ in hemolytic activity, the *C4B* about four times greater. Comparison of the nucleotide sequences of *CYP21A2* and *CYP21A1P* (113,114) shows that any possible expression of *CYP21A1P* is precluded by a number of irregularities in the open reading frame.

The *CYP21A2* and *CYP21A1P* genes are about 5kb long, the *C4A* gene about 21kb and the *C4B* gene in two size variants 21kb and 14.6kb long. They occupy an 80-kb segment in the order *C4A*–*CYP21A1P*–*C4B*–*CYP21A2*, all oriented with the sense strand reading left to right. This configuration is itself hypothesized to have come about by a past recombination event or events in mammalian evolution occurring for an original single *C4*\*–*CYP21A2*\* pair and the duplication going to fixation.

Two types of genetic instability apparently exist to generate mutations at the rates maintaining the high incidence of steroid 21-hydroxylase deficiency. The first is created by the symmetry of the arrangement, which predisposes it to misalignment and unequal crossing over in meiosis, producing imbalanced complementary chromosomes, one carrying a further duplication and the other with a deletion of one type of gene or (most often) a *C4*–*CYP21A2* unit. In the second, homologous genes are subject to a less well-understood process involving the nonreciprocal transfer of (generally shorter) DNA sequences from *CYP21A1P* to *CYP21A2*, called gene conversion (115).

Both classic and nonclassic 21-hydroxylase deficiency are inherited in a recessive manner as allelic variants. Classic 21-hydroxylase deficiency results from the presence of two severely affected alleles and nonclassic 21-hydroxylase deficiency results from the presence of either two mild 21-hydroxylase deficiency alleles or one severe and one mild allele.

**FIGURE 87-7** Incidence of nonclassic 21-hydroxylase deficiency in comparison with some other disease incidences. (From Reference (108).)

**87.2.3.1 Human Leukocyte Antigen Linkage.** Genetic linkage between HLA and 21-hydroxylase was reported by Dupont and coworkers in 1977 (58,116–119). This linkage, initially useful in family studies, has been supplanted by molecular genetic studies.

The initial molecular genetic analysis of 21-hydroxylase deficiency made use of the known associations of the disorder with specific HLA antigens B and DR and serotypes of C4, the fourth component of serum complement. In particular, salt-wasting 21-hydroxylase deficiency is often (15–20% of all alleles) associated with an extended HLA haplotype, A3, Bw47, DR7, which is half-null for C4 (i.e. only one serum isoform instead of two normally present) (120–122). Using a probe for 21-hydroxylase, DNA samples obtained from normal individuals and from steroid 21-hydroxylase deficiency patients with HLA types Bw47/- and Bw47/Bw47 were tested. Southern blotting after digestion with several restriction endonucleases showed that normal DNA samples yielded two fragments hybridizing with the probe at equal intensity. By contrast, DNA samples from the HLA-Bw47 heterozygous 21-hydroxylase-deficient individuals showed a reduced intensity of one band and the DNA sample from the HLA-Bw47 homozygous individuals showed a total absence of that band (123). Additionally, the hormonally normal status of individuals missing the CYP21A1P (originally termed the CYP21A gene) fragment after hybridization and Southern blotting suggested the gene was not necessary for adrenal steroid 21-hydroxylating function (124,125).

The deletions within the HLA-A3; Bw47; DR7 and HLA-A1; B8; DR3 haplotypes were further characterized: the HLA-A1; B8; DR3 haplotype was found to be missing the C4A gene next to the absent CYP21A1P, and the HLA-A3; Bw47; DR7 haplotype to be missing C4B, next to the absent B gene (CYP21A2) (124,126,127). Physical mapping of this region showed that each repeat unit C4A + CYP21A1P and C4B + CYP21A2 spans about 30 kb and that within each unit the C4 and CYP21 are only 3 kb apart.

The HLA-A1; B8; DR3 haplotype is not uncommon, occurring in about 5% of all normal chromosomes (128) and has itself been negatively associated with 21-hydroxylase deficiency. Disproportion in length between a single C4–CYP21A2 compared with the duplicated units on most other haplotypes may discourage recombination and lead to increased stability of this and other haplotypes such as the “Sardinian” haplotype without duplication of C4 and CYP21A2 genes, conjectured to be an ancestral type (129).

Further examination of the DNA sequence of HLA-A3; Bw47; DR7 identified a crossover site for the past recombination event within the CYP21A2 gene, such that misalignment between CYP21A2 and CYP21A1P produces a nonfunctional chimeric gene. Of significance for Southern blotting restriction fragment length polymorphism (RFLP) studies, chimeric fragments may also

be created with lengths established by the distance to the first restriction sites upstream and downstream of the splice, and these can coincide in some instances with standard fragment lengths, wrongly suggesting the presence of DNA that is actually deleted. Proper interpretation of such banding patterns may present considerable difficulty (130–133). A more accurate analysis can be made with the use of multiple and widely spaced restriction digests; however, the use of RFLP and dot blot analysis has been replaced in favor of newer polymerase chain reaction (PCR) techniques. Rapid allele-specific PCR techniques have been proved to be less time consuming and more sensitive, but must be used in conjunction with Southern blot analysis in order to distinguish between deletions and gene conversions (134). Pulsed field gel electrophoresis and multicolor fluorescence in situ hybridization (FISH) have also been used to identify deletions and duplications (135,136). Recently, a new rapid analysis method has been developed to detect point mutations and large deletions by PCR (137).

Duplication/deletion events have created the rearrangements observed in the HLA-A1; B8; DR3 and the A3; Bw47; DR7 haplotypes (126). The HLA-Bw47 type is extremely rare in mixed white populations. In the northern United Kingdom, where it has a higher natural frequency, deletion/duplication events are also found to account for a higher proportion of cases of 21-hydroxylase deficiency CAH, in the range of 30–35%.

The haplotype HLA-B14, DR1 has been found to be associated with from 36% (138) to over 85% (139) of cases of nonclassical 21-hydroxylase deficiency in different groups according to ethnic composition. In individuals with this haplotype, an extra C4B gene (122,124,140) and an extra CYP21A1P or CYP21A1P-like gene (124,141) have been identified. The mutations present in the active CYP21A2 gene on this haplotype have since been identified (142), and expression studies have confirmed that the enzyme expressed has 20–50% of normal activity (143).

**87.2.3.2 Deletions and Gene Conversions.** HLA genotyping is a possible means of diagnosis but has now been superseded by direct molecular analysis of the 21-hydroxylase locus. Allele-specific amplification of the CYP21A2 gene utilizing PCR is the preferred method of mutation analysis (134).

In most populations, CYP21A2 mutations in the form of deletions generally appear to comprise about 20% of classic 21-hydroxylase deficiency alleles (144–147), the majority of which have associated deletions of a C4B gene. The majority of deletions stretch from a region between exons 3 and 8 of CYP21A1P to a corresponding base pair in CYP21A2. Since the hybrid genes contain one or more mutations associated with the pseudogene, they are nonfunctional (133).

Most haplotypes carrying CYP21A2 alleles that cause classic CAH do not have associated RFLPs; thus, the presence of these mutations cannot be detected by Southern

blot hybridization. Fine analysis of these mutations has in many cases identified mutated sequences corresponding to the base sequences at the homologous positions in the pseudogene (Table 87-1). These are apparently the result of gene conversions. All the deleterious mutations resident on the pseudogene have by now been identified, singly or in combination, in mutant *CYP21A2* genes.

An early-identified conversion was the point mutation changing isoleucine-172 to asparagine, possibly affecting interactions between the P450 protein and the membrane of the endoplasmic reticulum (148). Another point mutation produces a stop codon (nonsense mutation) and premature termination at position 318 (149), whereas another more extended conversion spanning the third to the sixth exon was also identified (150). All patients with the nonsense mutation have salt-wasting disease, whereas the patients with the asparagine-172 mutation retain limited ability to synthesize aldosterone (manifested as simple virilizing disease, often with elevated plasma renin-to-aldosterone ratio). Substitution of valine-281 to isoleucine produces a partially functional mutant cytochrome P450c21 and is the basis of non-classical 21-hydroxylase deficiency associated with the haplotype HLA-B14, DR1 (142). In the larger rearrangement involving exons 3–6, transfer of the 8-bp deletion from *CYP21A1P* shifts the reading frame of translation and prevents synthesis of a functional protein; thus, it is associated with salt-wasting disease (150).

Gene deletions, nonsense and frameshift mutations, and certain amino acid substitutions result in salt-wasting alleles, one nonconservative substitution causes a simple-virilizing allele, and conservative substitutions are associated with a nonclassic allele. Conversely, some patients with documented episodes of salt-wasting in infancy develop the ability to synthesize adequate amounts of aldosterone later in life (151). This recovery might result from increased expression of a poorly active P450c21 or from individual variations in level of some other P450 enzyme, distinct from P450c21, with some 21-hydroxylase activity (152,153).

Although patients with 21-hydroxylase deficiency are often compound heterozygotes, the patient's phenotype is usually determined by the least severely affected allele. Thus, there is generally a good correlation between the severity of the clinical disease and the discrete mutations observed (154,155). Several studies evaluating the phenotype–genotype relationship in 21-hydroxylase deficiency, however, have demonstrated that there is often a divergence in phenotypes within mutation-identical groups, for reasons not yet known (134,156). Some patients who bear the V281L mutation associated with nonclassic CAH on one allele and a deletion on the other have, in fact, by hormonal diagnosis simple virilizing or salt-wasting classical 21-hydroxylase deficiency (54). Two HLA-identical brothers were reported who have mutations in intron 2 and exon 10 of *CYP21A2*, but one was shown to have salt-wasting CAH, whereas the other

retained the ability to synthesize aldosterone and was diagnosed to be a simple virilizer (53). The most recent analysis of 182 unrelated families from Finkelstein et al. demonstrated that the genotype–phenotype concordance is 90.5% for salt-wasting CAH, 85.1% for simple-virilizing CAH, and 97.8% for nonclassic CAH (157). Rocha et al. recently showed that CAG repeats in the androgen receptor has a great influence on variability in virilization of external genitalia of CAH women (158). Further studies in promoters, surrounding genes, transcription factors, transport proteins, and other modifiers may reveal a cause for the discordance in phenotype.

De novo mutations have been identified consistent with the operation of the two mechanisms above (159–162); thus, these mechanisms appear to explain the high frequency of 21-hydroxylase deficiency and will probably continue to generate numbers of mutations far in excess of the few random cytochrome P450c21 mutations that appear to have occurred.

### 87.3 STEROID 11 $\beta$ -HYDROXYLASE DEFICIENCY

Abnormal adrenal steroid secretion attributable specifically to impeded 11 $\beta$ -hydroxylation was first reported by Eberlein and Bongiovanni (163). The variable hormonal profiles of patients with 11 $\beta$ -hydroxylase deficiency eventually led to the identification of two 11 $\beta$ -hydroxylase isoenzymes encoded by two genes, *CYP11B1* and *CYP11B2* (164–166). *CYP11B1* encodes 11 $\beta$ -hydroxylase enzyme, which catalyzes the final step in cortisol synthesis and is consequently regulated by ACTH. The final steps in aldosterone biosynthesis are catalyzed by aldosterone synthase, which is encoded by *CYP11B2* and is regulated by angiotensin II and potassium.

The characteristic steroid profile of 11 $\beta$ -hydroxylase deficiency (P450c11) owing to mutations in *CYP11B1* shows elevated 11-deoxycortisol (compound S) and DOC in the serum, with marked urinary elevation of the corresponding tetrahydro metabolites, THS and THDOC, and complete absence of any 11-oxygenated C<sub>19</sub> or C<sub>21</sub> steroids in the blood or urine.

Hypertension with hypokalemic alkalosis is the single clinical feature distinguishing 11 $\beta$ -hydroxylase from 21-hydroxylase deficiency, yet it is not uniformly present. DOC has been thought to be the causative agent of hypertension (167,168), but this is not certain. While it has moderately potent MC effects, causing sodium retention, plasma volume expansion, and suppression of PRA, DOC may be elevated in 11 $\beta$ -hydroxylase-deficiency patients who are normotensive (169) or only mildly elevated in hypertensive patients (170,171). In addition, neither does intravenous DOC infusion uniformly induce hypertension in control subjects (172) nor does suppression of DOC always lead to remission of hypertension in 11 $\beta$ -hydroxylase deficiency patients (173). MC excess and hypertension is not necessarily proportional to the

TABLE 87-1 Steroidogenic Enzymes: Gene Mutation Table

	E1	4. Missense mutation	P30L	Nonclassical (NC) phenotype
				(Tusie Luna et al., 1991) (conversion)
	E1	5. Missense mutation	P30Q	SW allele
	E1	6. Frameshift mutation	Y47 Δ 1nt	Deletion of thymidine at nt 141 leads to L51X
				(Krone et al., 1999)
	I1	7. Aberrant splicing of intron 1	W23X nt 295AØG	
				(Lajic and Wedell 1996)
	E2	8. Missense mutation	G90V	Spanish patient
	I2	9. Abberant splicing of	387* GØA	Intron 2 splice donor site; intron 2 Chinese patient
				(Lee et al., 1998)
	I2	10. Aberrant splicing of	656*	Part of intron (end intron 2 conversion) A/CØG 19 bases retained in mRNA processing
				Higashi et al., 1988
	E3	11. Nonsense mutation	Y97X	
				(Krone et al., 1998)
	E3	12. Missense mutation	P106L	NC allele
				(154)
	E3	13. 8 nt-deletion (conversion)	G110Δ8 nt	Frameshift: 20-AA + stop
				(150)
	E3	14. Missense mutation	R132C	
				(Minuto et al., 2011)
	E3	15. Missense mutation	H119R	NC
				(Concolino et al., 2009)
	E4	16. 1-nt deletion	C169Δ1 nt	Frameshift
				(Witchel et al., 1999)
	E4	17. Missense mutation	I172N	Affects anchoring in (conversion) membrane
				(148)
	E4	18. Missense mutation	I49C	
				(Minuto et al., 2011)
	E5	19. Missense mutation	G178A	SW allele
				(Lobato et al., 1999)
	E5	20. Three-base deletion	ΔE 196	Deletion of nucleotides 1158–1160
				(Nikoshkov et al., 1998)
	E5	21. Missense mutation	I194N	
				(Concolino et al., 2009)
	E6	22. Cluster (conversion)	I236N V237E M239K	2 more charges added in region with multiple charged residues
				(Higashi et al., 1988)
	E6	23. Missense mutation	R224W	NC
				(Concolino et al., 2008)
	E7	24. Missense mutation	V281L	Major NC mutation HLA-B14; DR1 associated
				(142) (Conversion)
	E7	25. Missense mutation	V281G	
				(156)
	E7	26. Missense mutation	G291S	AA substitution CØT at conserved positio
				(154)
			398*	At position +9 of intron (secondary effect?)
	E7	27. Missense mutation	G291C	
				(Lobato et al., 1999)
	E7	28. Missense mutation	L300F	
				(156)
	E7	29. Nonsense mutation	W302X	Finnish patient
				(Levo and Partanen, 1997)
	E7	30. Single base	F306 + 1nt	Frameshift: insertion (conversion) +T at codon 305–7
				(Harada et al., 1987)
	E7	31. Missense mutation	M283V	
				(Minuto et al., 2011)
	I7	32. Loss of splice donor	1784* GØC	Aberrant splicing site at Intron 7 Found in one SW patient
				(Wedell and Luthman, 1993)
	I7	33. Loss of splice donor	1785*TØG	Aberrant splicing site at Intron 7 Found in one NC patient
				(Ordóñez-Sánchez et al., 1998)
	E8	34. Nonsense mutation	R316X	Chinese patient
				(Lee et al., 1998)
	E8	35. Nonsense mutation	Q318X	Conversion
				(149)

**TABLE 87-1 Steroidogenic Enzymes: Gene Mutation Table—cont'd**

	Exon/Mutation Name/Type	Gene AA	Intron Comments	Reference
	E8 36. Frameshift	S330 $\Delta$ 10 nt	Chinese patient	(Lee et al., 1998)
	E8 37. Missense mutation	R339H	NC allele	(Helmberg et al., 1992c)
	E8 38. Missense mutation	R354H	0% activity in transfected cells	(Lobato et al., 1999)
	E8 39. Missense mutation	R354C		(156)
	E8 40. Missense mutation	R356W	Radical AA substitution may impair redox interactions	(Chiou et al., 1990) (conversion)
	E8 41. Missense mutation	R356P	May impair redox interactions	(Lajic et al., 1997)
	E8 42. Missense mutation	R356Q	May impair redox interactions	(Lajic et al., 1997)
	E9 43. Missense mutation	E380D		(Kirby-Keyser et al., 1997)
	E9 44. Duplication	V397 + 16nt	Frameshift, Chinese patient	(Lee et al., 1998)
	E9 45. Nonsense mutation	W405X		(Wedell and Luthman, 1993)
	E9 46. Missense mutation	D407N	NC	(Concolino et al., 2008)
	E10 47. Missense mutation	G424S	Brazilian patient	(Billerbeck et al., 1999)
	E10 48. Missense mutation	P453S+(P453) and non-conserved (P105) residue	NC allele plus P105L AA substitution of conserved	(Owerbach et al., 1992; (154)
	E10 49. Frameshift mutation	P475 $\Delta$ 1nt		(Ordonez-Sanchez et al., 1998)
	E10 50. Missense mutation	R483P		(Wedell and Luthman, 1993b)
	E10 51. Compound frameshift	R483 $\Delta$ 1 nt	Replaces last 11 AA and extends mutation protein by a further 45 AA	(154)
	E10 52. Missense mutation	E431K		(Minuto et al., 2011)
	E10 53. 2-base deletion	g.2511_2512	Frameshift del GC	(Minuto et al., 2011)
CYP11B1	E1 1. Nonsense mutation	Q19X	Caucasian patient	(Merke et al., 1998)
	E1 2. Single base deletion	32 $\Delta$ 1nt	Frameshift	(Curnow et al., 1993)
	E1 3. Missense mutation	P42S	Compound heterozygote	(176)
	E2 4. 28-nt deletion	105 $\Delta$ 28 nt	Deletion of codon 105 to first nt to 113	(Skinner et al., 1996)
	E2 5. 5-nt duplication	dup5 nt		(Skinner et al., 1996)
	E2 6. Nonsense mutation	W116X	Japanese (consanguineous)	(201)
	E2 7. 5-nt duplication	121-2dup	Frameshift Asian (Kenya) patient	(202)
	E2 8. Missense mutation	V129M	Compound heterozygote and 28-nt deletion	(203)
	E2 9. Missense mutation	W116G	Classic	(342)
	E2 10. Missense mutation	M88I	Nonclassic	(342)
	E3 11. Missense mutation	N133H	Compound heterozygote	(176)
	E3 12. Nonsense mutation	K174X	Premature termination	(Curnow et al., 1993)
	E3 13. Missense mutation	A165D	Classic	(342)
	E3 14. Missense mutation	P159L	Nonclassic	(342)
	E3 15. Missense mutation	R141X		(206)
	E4 16. Nonsense mutation	W247X	Premature termination	(Curnow et al., 1993)
	E4 17. Six base deletion	K254_A259 del	Frameshift	(342)
	E5 18. Missense mutation	G267R		(Skinner et al., 1996)
	E5 19. Missense mutation	G267D		(Skinner et al., 1996)
	E5 20. Missense mutation	T318T	G to C in the last codon of exon 5. mRNA not detected in vitro	(Chabre et al., 2000) (splicing)
	E5 21. Missense mutation	T318M	Parents Yemenite (first cousins)	(Curnow et al., 1993)
	E5 22. Missense mutation	T318R	Caucasian patient	(Merke et al., 1998)
	I5 23. Aberrant splicing	G to A	African-American	(Merke et al., 1998)
	E6 24. Missense mutation	T319M		(176)
	E6 25. Missense mutation	A331V		(203)
	E6 26. Nonsense mutation	Q338X	Parents both Indian Sikh	(Curnow et al., 1993)
	E6 27. Nonsense mutation	Q356X	Number of other genetic defects; African-American	(Curnow et al., 1993)
	E6 28. Nonsense mutation	Q356X	Premature termination	(Skinner et al., 1996)

degree of hypokalemia (173) and cases showing lack of suppression of PRA (considered a hallmark of this defect) have been noted (39,174). More recently, the role of DOC metabolites such as 18-hydroxy-DOC has been considered, but the specific adrenocortical factor—if any—operative in the hypertension seen in this disorder remains to be established (173,175).

As in 21-hydroxylase deficiency, excess fetal androgen production causes prenatal virilization of females, resulting in ambiguous external genitalia with normal female internal reproductive organs. In newborn males with 11 $\beta$ -hydroxylase deficiency, the external genitalia may be normal, but in either sex, virilization ensues postnatally if the disorder is untreated. There is no direct correlation between the degree of virilization and hypertension (173).

### 87.3.1 Nonclassic 11 $\beta$ -Hydroxylase Deficiency

Mild, late-onset, and even cryptic forms of 11 $\beta$ -hydroxylase deficiency have been reported (39,176–183). Nonclassic 11 $\beta$ -hydroxylase deficiency has been diagnosed in normotensive children with mild virilization (184) or precocious pubarche (183) and in adults with signs of hyperandrogenemia (176) as well as a woman with infertility (185). Despite a hormonal profile consistent with 11 $\beta$ -OHD, mutations in the *CYP11B1* gene may not always be present (176). As in 21-hydroxylase deficiency, this clinical variability may represent allelism at the 11 $\beta$ -hydroxylase structural gene locus, but biochemical investigations of obligate heterozygote parents did not find a consistent defect either in the baseline state or with ACTH stimulation with some, but not all, showing an elevated 17-OHP-to-cortisol or 11-deoxycortisol-to-cortisol ratio (186).

**87.3.1.1 Epidemiology.** Steroid 11 $\beta$ -hydroxylase deficiency has been found in roughly 5% of cases of CAH (96,187), a figure that probably applies worldwide. In Israel, however, 20% of CAH cases identified over a period of 16 years were attributable to 11 $\beta$ -hydroxylase deficiency (188), for a frequency of approximately 1 per 60,000 live births with a corresponding heterozygote frequency of 1 in 123. Many of the families in which 11 $\beta$ -hydroxylase deficiency occurred could claim forebears from a cluster of old Jewish settlements in north Africa (some dating from before AD 70) and a founder effect originating from within one of these communities or introduced from indigenous Berber people is most likely (189). Turkish Jews, who may formerly have engaged in increased intermarriage, are also known to have higher incidences of the 11 $\beta$ -hydroxylase deficiency (173,184,190) and were also thought likely to carry a recurring mutation. Molecular genetic studies have confirmed the presence of a single *CYP11B1* mutation in each of these groups (191,192). Unlike the common nonclassic form of 21-hydroxylase deficiency, the nonclassic form of 11 $\beta$ -hydroxylase deficiency is very rare.

### 87.3.2 Aldosterone Synthase Deficiency

Aldosterone synthase (*CYP11B2*) not only has 11 $\beta$ -hydroxylase activity but also converts corticosterone to 18-hydroxycorticosterone by 18-hydroxylase and subsequent 18-oxidation of 18-hydroxycorticosterone to aldosterone by 18-oxidase (see Figure 87-1). Defects in aldosterone synthase activity are termed aldosterone synthase deficiency I or II depending on the production of 18-OH corticosterone, which is increased only in type II. Aldosterone synthase deficiency type I occurs less frequently than type II, typically results in

little or no aldosterone production, and is phenotypically more severe than aldosterone synthase deficiency type II (193,194). Defects in aldosterone synthase activity are inherited as autosomal recessive conditions.

Formerly, biochemical studies by Hall and his group on bovine enzymes had indicated that 11 $\beta$ -hydroxylase and two closely related activities, originally termed corticosterone methyloxidase I (18-hydroxylase) and corticosterone methyloxidase II (18-oxidase), all resided in one protein (195); thus, corticosterone methyloxidase deficiency I and II was first investigated as a possible allelic variant of 11 $\beta$ -hydroxylase deficiency. In 1996 Ulick suggested changing the nomenclature to aldosterone synthase deficiency type I and II since it was known that one enzyme, aldosterone synthase (P450c11Aldo), catalyzed all three final steps in aldosterone biosynthesis (196).

Aldosterone synthase deficiency types I and II cause a salt-wasting syndrome that presents with hyponatremic hyperkalemia and dehydration in an infant. Both types of aldosterone synthase deficiencies cause an increase in plasma levels of DOC and corticosterone. The diagnosis of aldosterone synthase deficiency type I can be determined by measuring increased precursor to product ratios of corticosterone/18-hydroxycorticosterone, whereas the diagnosis of aldosterone synthase deficiency type II is established by measuring increased precursor to product ratios for 18-oxidase activity, that is, the 18-hydroxycorticosterone/aldosterone ratio in serum, or in the urine the ratio of their major respective metabolites, 18-hydroxytetrahydro-11-dehydrocorticosterone (18-OH-THA) to tetrahydroaldosterone.

### 87.3.3 Molecular Genetics

The molecular genetic basis of steroid 11 $\beta$ -hydroxylase deficiency and of two related disorders, aldosterone synthase deficiency I/II and dexamethasone-suppressible hyperaldosteronism (DSH), has been elucidated (197).

CYP11B1 and CYP11B2, encode two mitochondrial cytochrome P450 isoforms (93% amino acid sequence similarity), cytochrome P450c11 and cytochrome P450c11Aldo, with important differences in function consistent with the separate cell expression patterns and distinct regulation of the genes. CYP11B1 is expressed in all zones of the adrenal cortex and its regulation is ACTH dependent, whereas CYP11B2 is expressed exclusively in the zona glomerulosa and is regulated by angiotensin II and potassium ion. Cytochrome P450c11 and cytochrome P450c11Aldo show considerable sequence similarity with cholesterol side-chain cleavage enzyme (cytochrome P450scc), also located in the mitochondrial inner membrane; they are grouped together in the same family, family XI (111,198).

The structural gene for the 11 $\beta$ -hydroxylase enzyme (CYP11B1) was cloned and sequenced and then localized to the long arm of chromosome 8q22 (164,199).

CYP11B2 was eventually mapped to chromosome 8q24.3 (166,199). The two genes are separated by about 40 kb of DNA.

Mutations in the CYP11B1 gene cause steroid 11 $\beta$ -hydroxylase deficiency, which affects cortisol synthesis and produces virilizing CAH with hypertension (see Table 87-1), and mutations in the CYP11B2 gene cause aldosterone synthase deficiency types I and II. A third clinical condition involving these genes is a hypertensive disorder called DSH, or GC-remediable aldosteronism (GRA). DSH is hormonally characterized by ACTH-dependent aldosterone synthesis, which is the result of the creation of a chimeric gene by fusion of the CYP11B1 and CYP11B (197,200).

**87.3.3.1 CYP11B1.** The first mutations in the CYP11B1 gene were sought in cases of steroid 11 $\beta$ -hydroxylase deficiency occurring in Israel, where the defect is more prevalent than elsewhere. In a number of cases in Israel, family origins were traced back to Moroccan Jewish settlements, among which it was assumed that a founder mutation occurred or was introduced (189). Genetic analysis of these families discovered the recurrence of a single mutation in the CYP11B1 gene, a point mutation in exon 8 of the gene (9 exons), changing the specification of codon 448 from arginine to histidine (191). The second CYP11B1 mutation to be identified was in a pedigree of Turkish Jewish origin. This mutation, a 2-base insert in exon 7, shifts the reading frame to code for an incorrect 77-amino acid continuation (resulting in a mutant protein slightly shorter than the normal 503 residues), obliterating the heme-binding domain, and thus makes a completely dysfunctional product. Further studies analyzing DNA from individuals of diverse ethnic backgrounds identified a series of eight distinct mutations—four missense mutations, a frameshift mutation (a single-base deletion) and three point mutations specifying premature termination. Expression (by transfection assay) of the Moroccan mutation and the four other missense mutations produced mutant proteins that were in all cases devoid of activity. It was noted that of the 10 mutations reported in these three studies, seven are in exons 6 to 8, but if this was nonrandom, it was not known whether it was conditioned by the location of functionally important amino acid residues in this region of the enzyme polypeptide or whether there was any tendency for mutations to develop latent in specific base sequences in this region of the gene.

Many reports have since appeared in the literature, many of which have identified patients with homozygous mutations (201–205). In the first of such reports, a Japanese patient was found to be homozygous for a point mutation changing the specification of codon 116 from tryptophan to termination (W116X). The researchers assayed this mutation in a cell expression system and found predictably no enzymatic activity in the mitochondria, and they sequenced the patient's CYP11B2 gene and found it entirely normal (201). In

another report, CYP11B1 exons were selectively amplified by PCR and then screened individually for sequence changes by single-strand conformation polymorphism (SSCP) analysis, which revealed an unusual pattern for the exon 2 segment. Cloning and sequencing identified a 5-base duplication between codons 121 and 122, and further analysis confirmed that it occurred in both alleles in the patient. Causing a frameshift and early termination (exon 3), this mutation was thought to explain the phenotype, but exon 8 (whose SSCP segment also differed from controls) was found to carry two additional point mutations. Although presumed to be irrelevant to the present case, it was speculated whether these exon 8 mutations might have occurred previously and what their independent effects would be. While the first corresponds to a conservative substitution, valine to alanine (V348A), the second mutation (also confirmed to be on both alleles) corresponds to substitution of a histidine for a highly conserved arginine near the heme-binding domain (R427H) and would very likely compromise enzymatic activity (202). To date, more than 50 different mutations in the CYP11B1 gene have been identified. A recent multicenter study identified seven new mutations in the CYP11B1 gene. Three mutations (p.W116G, p.A165D and p.K254\_A259 del) were associated with classic disease and four mutations (p.P159L, p.M881, p.R366C and p.T401A) were associated with nonclassic disease. These findings doubled the number of mild CYP11B1 gene mutations previously described associated with mild or nonclassic 11 $\beta$ -hydroxylase deficiency. The data was validated with in vitro expression studies (342).

**87.3.3.2 CYP11B2 (Aldosterone Synthase Gene).** Isolated defects in the terminal steps of aldosterone synthesis produce a salt-wasting syndrome in infancy (197,206). Early clinical studies in aldosterone synthase deficiency were carried out on 12 patients from an isolated community of Iranian Jews who presented with a wide range of clinical severity (207). Later a genetic study designed to examine DNA from these patients using a probe for CYP11B1 was undertaken. With this probe, a specific banding pattern was found to correlate with the presumptive genotypes of affected and carrier family members, suggesting the presence of a mutation within or very closely neighboring the CYP11B1 gene locus (208).

Initial characterization of CYP11B2 showed the gene to have an intact open reading frame (209) and marked divergence of 5' regulatory sequences relative to CYP11B1 (165,209). Evidence for expression of the CYP11B2 gene was first found in a cDNA library derived from human aldosteronoma tissue, which was then screened and cloned corresponding to the transcript of the CYP11B2 gene found (210). It was then shown that CYP11B2 was expressed in normal adrenal glands and that it was in fact the gene encoding the required enzyme for the completion of aldosterone synthesis (211). This reopened analysis of the Iranian salt-wasting families with aldosterone

synthase defects: all of the affected members of these kindreds were found to be homozygous for a double mutation in CYP11B2: R181W and V386A (212,213). When these were individually expressed in a cell culture system, the R181W mutant enzyme showed reduced 18-hydroxylase, undetectable 18-oxidase, and intact 11 $\beta$ -hydroxylase activity. In addition, there was V386A (this amino acid is normal at this position in CYP11B1) reduced 18-hydroxylating activity—consistent with aldosterone synthase deficiency type II. Family members homozygous for either mutation alone were asymptomatic. No mutations were found in any CYP11B1 genes (214). Characterization of the CYP11B2 genes in DNA from three other Iranian Jewish families found the identical mutations (213).

Recently, additional mutations in patients presenting with aldosterone deficiency type II have been identified: an amino acid substitution (T318M) (215), a deletion of codon 173 in exon 3 (216), and a gene conversion in which 500bp of exons 3 and 4 in CYP11B2 were changed to the corresponding sequence of CYP11B1 (217). To date there have been three patients with aldosterone synthase deficiency type II who did not carry any detectable mutation in their entire CYP11B2 alleles (206).

A total of 10 mutations causing aldosterone synthase deficiency type I have been detected in the CYP11B2 gene (193,194,218–221), with five new mutations reported in 2010 by Nguyen (222). One study reported an individual homozygous for two deleterious mutations and a polymorphism, whose hormonal phenotype was consistent with aldosterone synthase deficiency type I, but whose in vitro transfection data was typical of the aldosterone synthase deficiency type II (194). The unexplained discrepancy between the in vitro activity and the clinically observed phenotype demonstrates the need for further phenotype/genotype studies.

**87.3.3.3 CYP11B1–CYP11B2 Chimeric Gene.** The existence of a familial form of hyperaldosteronism has been known for some years in which the prompt sustained reduction of aldosterone levels by the GC dexamethasone is the basis for diagnosis and treatment and has an autosomal dominant mode of transmission. This particular type of aldosteronism, known as DSH or GC-remediable hyperaldosteronism (GRH or GRA, as noted previously), also has as a specific biochemical index: abnormal serum and urinary elevations of 18-hydroxy and 18-oxocortisol, steroids normally synthesized in very limited amounts by the adrenal cortex. The molecular genetic basis for DSH in all reported cases is the creation of a fusion gene, because of unequal crossing over, between CYP11B1 and CYP11B2, in addition to a normal copy of each flanking the chimeric gene. This mutation combines an ACTH-responsive regulatory region with coding sequences for partial or full (depending on the precise location of the crossover) steroid 18-hydroxylating and 18-oxidating functions (200,212,223). The chimeric

gene has 5' and 3' ends that correspond to CYP11B1 and CYP11B2, respectively, and the points of transition are all located between intron 2 and exon 4 (197). This results in the expression of a hybrid cytochrome P450 at high levels in the zona fasciculata that synthesizes aldosterone from corticosterone in a pattern following ACTH cyclicity and at levels inducing the pathology, as well as synthesizing 18-oxocortisol from cortisol normally present, producing the quantitative abnormality of a 17 $\alpha$ , 18-dihydroxysteroid. Since a functional excess is involved, it is sufficient that the fusion gene be present on one chromosome, hence the autosomal dominant mode of expression.

The situation of CYP11B genes has some similarity to that of CYP21 genes (homology: CYP21/21P 97% and CYP11B1/B2 93%; spacing on the chromosome: CYP21P–CYP21 30kb and CYP11B2–CYP11B1 30–45 kb), but crossover events for CYP11B genes appear to be much less frequent. The creation of a chimeric gene is not a priori the only type of event able to generate the hormonal features and inheritance pattern of DSH. Plausibly nonreciprocal transfers, whether of an ACTH-regulatory segment from the *CYP11B1* to the *CYP11B2* gene or conversely of a coding segment specifying 18-oxidating activity from the *CYP11B2* to the *CYP11B1* gene, could occur.

## 87.4 3 $\beta$ -HYDROXYSTEROID DEHYDROGENASE DEFICIENCY

The enzyme 3 $\beta$ -HSD is necessary for the synthesis of all adrenal and gonadal steroids beyond the relatively inactive  $\Delta^5$  precursors. In addition to 3 $\beta$ -hydroxysteroid dehydrogenation, the enzyme also performs subsequent 3-oxosteroid isomerization, and is alternately termed  $\Delta^5$ , $\Delta^4$ -isomerase. First described in 1962 by Bongiovanni, 3 $\beta$ -HSD deficiency appears to have a monogenic autosomal recessive mode of transmission based on pedigree analysis (224–226).

As gonadal 3 $\beta$ -HSD enzymatic activity is also reduced (although not always equally with the adrenal defect), gonadal androgen production is deficient. In genetic males, incomplete genital development results in sexual ambiguity at birth. By contrast, in affected females, the very high levels of circulating DHEA—and perhaps some peripheral conversion of DHEA to more potent androgens—may produce a limited androgen effect (restricted to clitoral enlargement and rarely, labial fusion).

A high ratio of  $\Delta^5$  to  $\Delta^4$  steroids, characterized specifically by elevated serum levels of the  $\Delta^5$ -steroids pregnenolone, 17-hydroxypregnenolone, and DHEA, and increased excretion of the  $\Delta^5$  metabolites pregnanetriol and 16-pregnenetriol in the urine, is diagnostic for this enzyme disorder.

Deficient aldosterone production in cases of a complete or near-complete 3 $\beta$ -HSD enzyme block results in salt wasting; in other cases, the ability to conserve sodium has been intact (85,224–236). Thus, in 3 $\beta$ -HSD

deficiency, as in 21-hydroxylase and 11 $\beta$ -hydroxylase deficiency, there is a phenotypic spectrum for each clinical feature, and salt wasting may be present to some degree (226). As with the two other common defects, it is not possible to judge the degree of severity of the 3 $\beta$ -HSD enzyme defect based on the appearance of the external genitalia at birth.

### 87.4.1 Nonclassic 3 $\beta$ -HSD Deficiency

As with 21-hydroxylase, nonclassic 3 $\beta$ -HSD is an attenuated enzyme defect with no major developmental abnormalities (79). Nonclassic 3 $\beta$ -HSD patients generally present with premature adrenarche, hirsutism, or oligomenorrhea (237). With postadrenarchal or peripubertal onset (234) it appears to affect the fasciculata–reticularis zones, thus the spared functioning of the glomerulosa ensures adequate salt retention (225). Sixty-minute ACTH testing with serum sampling at 0 and 60 min after administration of Cortrosyn (synthetic ACTH<sub>1–24</sub>, 0.25 mg IV) will reveal a 3 $\beta$ -HSD defect when serum  $\Delta$ -17-hydroxypregnenolone ( $\Delta^5$ -17P), DHEA levels, serum ratios ( $\Delta^5$ -17P), DHEA levels, serum ratios  $\Delta^5$ -17P: 17-OHP, and  $\Delta^5$ -17P:F are all more than 2 SD above the normal mean values (226). There are slight differences between investigators in the hormonal evaluation and definition of this enzyme defect (238).

Because several studies have not identified any mutations in the gene for 3 $\beta$ -HSD in nonclassic patients (239,240), it has been suggested that some cases may be an acquired defect or secondary to an intra-adrenal androgen excess (241,242). Further investigation is needed before nonclassic 3 $\beta$ -HSD deficiency may be classified as a genetic disorder.

**87.4.1.1 Epidemiology.** Severe defects of 3 $\beta$ -HSD (genital ambiguity at birth in both sexes, with or without salt wasting) are uncommon, and no geographic clustering or ethnic predominance has been discerned.

**87.4.1.2 Molecular Genetics.** The 3 $\beta$ -HSD enzyme is one of a diffusely defined group of NADH/NADPH-dependent enzymes performing reversible dehydrogenations on various organic compounds, with limited regions of substrate and cofactor-binding amino acid sequence similarity. The 3 $\beta$ -HSD enzyme is strongly NAD preferring. In experimental systems the 3 $\beta$ -HSD function requires the presence of NAD<sup>+</sup>, whereas the attendant  $\Delta^5$ , $\Delta^4$ -isomerization of 3-oxosteroids proceeds with the cofactor in either the oxidized (NAD<sup>+</sup>) or the reduced (NADH) state.

Two genes for 3 $\beta$ -HSD have been cloned and sequenced, HSD3B1 and HSD3B2, which encode two types of 3 $\beta$ -HSD enzyme, the type II enzyme expressed specifically in adrenal cortex and gonads (under appropriate separate regulation in each gland/cell type) and the type I enzyme, which is also the placental form, ubiquitously expressed in extraglandular tissues. There may be other isoforms of 3 $\beta$ -HSD not yet characterized (a type

III and IV have been found, for instance, in the rat, and a type III in the mouse) with other particular patterns of distribution and expression, such as in liver or adipose tissue.

HSD3B1 and HSD3B2 share more than 90% sequence homology and have been localized to chromosome 1p13.1 (243–245). All mutations causing  $\beta$ -HSD deficiency have been identified in the HSD3B2 gene only, and approximately 30 mutations have been identified to date. In 1995, Simard et al. identified 14 unique point mutations in the HSD3B2 gene in a study of 16 severely affected patients. There was no detectable  $\beta$ -HSD2 activity in the salt-wasting patients, while the enzymatic activity in non-salt-wasting patients due to missense mutations ranged from 1% to 10% (246). Gene conversion with  $\beta$ -HSD pseudogenes may account for some of the identified mutations.

## 87.5 STEROID 17 $\alpha$ -HYDROXYLASE/17,20-LYASE DEFICIENCY

A single microsomal P450 enzyme (P45017) catalyzes both the conversion of MCs to GCs by 17 $\alpha$ -hydroxylase activity and the conversion of GCs to sex steroids via 17,20-lyase activity. A 17 $\alpha$ -hydroxylase/17,20-lyase defect reduces conversion of steroid precursors to 17-hydroxy ( $C_{21}$ ) and consequently 17-keto ( $C_{19}$ ) steroids; adrenal secretion of GCs and sex steroids is thus diminished, and there is overproduction of 17-deoxysteroids. Plasma DOC and especially corticosterone are elevated. The defect was first identified by Biglieri and colleagues (247) in a genetic female and was first reported in a genetic male by New (248).

Corticosterone secreted in significant excess (producing plasma levels up to 60 times normal) appears to provide marginally sufficient GC activity for survival. The hypertension and hypokalemia are attributed to chronically elevated DOC and corticosterone. Untreated 17 $\alpha$ -hydroxylase deficiency in females at pubertal age results in primary amenorrhea and lack of development of secondary sex characteristics. Male undervirilization is evident at birth and includes incomplete Wolffian duct development (while müllerian structures are absent because of normal testicular production of AMH). Lack of androgens embryonically also fails to suppress the breast anlage in males, and gynecomastia is a prominent feature at puberty. Plasma gonadotropins are very high in both sexes postpubertally. While studies have shown renin levels to rise soon after GC treatment has begun and DOC levels to fall, it may take many months for normal aldosterone levels and proper glomerulosa function to be established (249).

### 87.5.1 Isolated 17,20-Lyase Deficiency

17,20-Lyase and 17 $\alpha$ -hydroxylase activities reside in the same protein (250) and is catalyzed on the same active

site (251); however, cases of isolated 17,20-lyase deficiency have been reported (252,253). Deficiency of 17,20-lyase causes a defect in the synthesis of  $C_{19}$  sex steroids in the adrenals and gonads (254,255). Affected individuals have phenotypically normal female genitalia at birth, regardless of the genetic sex, and usually present at adolescence with primary amenorrhea or lack of sexual development. Urinary pregnanetriolone, a metabolite of 17-OHP, is increased and increases further after ACTH and human chorionic gonadotropin (hCG) stimulation, the latter observation indicating concordance for the gene defect in both adrenal gland and testes (256). Testosterone or DHEA excretion does not rise appreciably. While 17 $\alpha$ -hydroxylase activity is often diminished in these patients, there is adequate activity to prevent MC hypertension and cortisol insufficiency.

In 1997, Geller et al. identified mutations (R347H and R358Q) in two patients with isolated 17,20-lyase deficiency (252). Using transfection and expression studies, the mutations were shown not to impair the affinity for 17-hydroxypregnenolone, but to inhibit electron donation that is crucial for lyase but not 17 $\alpha$ -hydroxylase activity (251). Both these CYP17 mutations were located in a region necessary for binding P450 oxidoreductase, which is responsible for electron donation to all microsomal cytochrome P450 enzymes. In addition, a mutation (F419C) preventing phosphorylation of P450c17 was identified in another patient, which also affects the ability of electron transfer and thus lyase function (257).

**87.5.1.1 Epidemiology.** Steroid 17 $\alpha$ -hydroxylase/17,20-lyase enzyme deficiency is generally rare. The total number of cases of 17 $\alpha$ -hydroxylase/17,20-lyase deficiency CAH recorded in 1992 was approximately 140–150 (258,259). A possibly greater incidence is suggested by Kater and Biglieri (260). As reflected in clinical case reports, defects in this enzyme, whether manifesting as combined 17 $\alpha$ -hydroxylase/17,20-lyase deficiency or as isolated 17,20-lyase deficiency, have appeared sporadically. Molecular studies have so far characterized over 70 mutations (257,261–264). One particular mutation appearing in widely dispersed families in North America belonging to the Anabaptist sect called Mennonites was first identified in the Friesland region of The Netherlands, where the sect first began (265–267). Biason-Lauber et al. (257) identified a homozygous mutation, R96W, in two unrelated Italian families, which may suggest a founder effect in the Italian population. In the Brazilian population 82% of mutant alleles are due to two mutations, suggesting a founder effect as well (263). Other populations with frequently reoccurring mutations that have been described are patients in Japan (268) and patients from East Asia (269–271).

**87.5.1.2 Molecular Genetics.** The structural gene for the microsomal cytochrome 17 $\alpha$ -hydroxylase and 17,20-lyase enzyme (P450c17) is termed CYP17 (198). This gene is on chromosome 10 (272), in the region 10q24-q25 (273), and exists in a single copy. The CYP17 gene

was shown to be identically transcribed in the adrenal gland and testis (274).

It was established early on such that the mutational pattern for CYP17 did not appear to include gross deletions or rearrangements in or near the gene locus (275). This was the second form of CAH after steroid 21-hydroxylase deficiency to have defects identified at the molecular level (258,259). To date there are more than 70 CYP17 locus mutations that have been characterized (see Table 87-1). It appears that the mutations occurring in this gene are random and not the results of any predisposing mechanism (276).

## 87.6 CONGENITAL LIPOID ADRENAL HYPERPLASIA

Deficient uptake of cholesterol into the mitochondria blocks conversion of cholesterol to pregnenolone at the rate-limiting step in steroid synthesis, leading to profoundly impaired production of all steroids. The condition was first described by Prader, who termed it lipid adrenal hyperplasia because of the characteristic appearance of the cholesterol-laden adrenocortical tissue (277). Gonadal hypogenesis or agenesis, severe fluid and electrolyte disturbances, and susceptibility to infection and addisonian pigmentation are seen; affected individuals often do not survive beyond infancy. Early reports include histologic examinations (278–280) and clinical descriptions (281), including one instance of a less severe phenotype (282). A case report reviewing 32 known cases in the literature describes a patient diagnosed in the newborn period who was successfully treated with MC and GC replacement therapy for 18 years (283).

### 87.6.1 Steroid Acute Regulatory Protein

The enzyme for cholesterol side-chain cleavage, known as cytochrome P450<sub>scc</sub>, or cholesterol desmolase, and encoded by CYP11A is the first enzymatic step in steroid synthesis, catalyzing the conversion of cholesterol to pregnenolone. The system of cholesterol side-chain cleavage consisting of P450<sub>scc</sub> and electron transfer proteins including adrenodoxin and adrenodoxin reductase was the most likely candidate for the cause of lipid CAH in initial studies. Southern blotting of DNA digests from affected individuals and family members found no gross abnormalities in the CYP11A gene (284). Mutations have been found, however, in the gene coding for the StAR, which is located on chromosome 8p11.2 (285,286). StAR is a phosphoprotein that is rapidly inducible by cAMP. While the mechanism of StAR is not thoroughly understood, its action facilitates transport of cholesterol into the mitochondria.

Two separate lesions, or events, described by Bose et al. (35) account for the variety of clinical observations in patients with congenital lipid adrenal hyperplasia, including the lack of virilization in the male and

spontaneous feminization in genetic females. The first event is the obvious absence of StAR-dependent steroidogenesis in the testes and adrenal glands. The second event is based on the observation of small amounts of steroid that can be made through basal StAR-independent steroidogenesis, which then stimulates trophic hormone secretion. These hormones stimulate the uptake of more extracellular cholesterol, which accumulates as lipid droplets, eventually damaging the cells and destroying any ability of steroidogenesis. Thus virilization does not occur in the male patient because the fetal testes are severely affected because of high levels of steroid synthesis. In contrast, in females, the ovaries produce no steroids until puberty, which occurs spontaneously and at which time follicular gonadotropin production through StAR-independent steroidogenesis enables spontaneous feminization.

**87.6.1.1 Epidemiology.** Congenital lipid adrenal hyperplasia is the rarest form of CAH. It has a significant mortality because of complete adrenal insufficiency. It appears to occur with lesser severity and more frequency among Japanese, Koreans (287), and Palestinian Arabs (288). Recent studies estimate the carrier rate in Japan for the most common StAR mutation seen in Asian populations (C898T) to be between 1 in 200 and 1 in 300 people (35,289).

**87.6.1.2 Molecular Genetics.** The StAR protein is a 30-kDa phosphoprotein first identified by Orme-Johnson in mouse adrenocortical cells (290). The synthesis of StAR protein occurs in the cytosol and is dependent on a protein kinase A signaling pathway. The first mutations in the StAR protein were C-to-T transitions that resulted in the premature insertion of a stop codon. Western analysis confirmed the mutant protein following cloning and expression of the cDNA (291). A report by Bose et al. (288) describes 15 patients with congenital lipid adrenal hyperplasia from 10 countries. In all three of the Japanese patients, four of the six unrelated alleles had the mutation, C898T, perhaps representing a founder effect. Similarly, in six patients of Palestinian origin, seven of the nine unique alleles had the R182L mutation in exon 5. Among the 15 mutations identified, A218V and L275P retained minimal activity in transfection studies, while the others had essentially no detectable activity. One patient was a compound heterozygote for A218V and L275P and had some StAR activity.

Until recently lipid CAH was known as a severe disorder characterized by significantly diminished or absent synthesis of all adrenal and gonadal steroids. In 2006, Baker et al. described three children from two families who presented with adrenal insufficiency at 2–4 years of age and where the males had normal genitalia. These patients were homozygous for StAR mutations V187M and R188C and in functional studies they retained approximately 20% of wild-type activity of the StAR protein (292). Hence a new disorder was described, termed nonclassic lipid CAH. In a more recent report

by Sahakitrungruang et al. four phenotypically different patients with partial loss-of-function mutations were described. The first three patients were phenotypic 46,XY males with various degrees of genital undermasculinization and adrenal insufficiency; the fourth patient was a 46,XX phenotypic female with late-onset adrenal crisis who was menstruating but had anovulatory cycles. Patient 1 was homozygous for the mutation 5033C>T, changing arginine 188 to cysteine (R188C). The mutation was previously described by Baker et al. (292). Patient 2 was a compound heterozygote for 6732T>C, changing leucine 260 to proline (L260P), and 6753T>C, changing phenylalanine 267 to serine (F267S). L260P was described in Swiss patients with classic lipoid CAH (293); F267S is a novel mutation. Patient 3 was compound heterozygous for R188C and tryptophan 250 stop mutation (W250X). Homozygous W250X was previously found in a Serbian 46,XY phenotypic female with classic lipoid CAH (294). Patient 4 was homozygous for the novel mutation 5780G>A, changing glycine to aspartic acid (G221D). In vitro studies demonstrated varied degrees of StAR activity, correlating to the severity of the phenotype. These recent reports of nonclassic StAR indicate that the disorder represents a spectrum of phenotypic severity with varied degrees of StAR activity.

It is of interest to note that most mutations found in StAR occur in the carboxy-terminal 40% of the protein, and that the mutations have recently been found to result in altered folding of the protein. Thus, the importance of the C-terminal portion may be significant in elucidating the mechanism of the StAR protein (295,296).

## 87.7 TREATMENT

### 87.7.1 Endocrine Therapy

The fundamental aim of endocrine therapy in CAH is to provide replacement of the deficient hormones. Since 1950, when Wilkins and coworkers discovered the efficacy of cortisone therapy for CAH due to 21-hydroxylase deficiency, GC therapy has been the key-stone of treatment for this disorder. GC administration both replaces the deficient cortisol and reduces ACTH release and overstimulation of the adrenal cortex, suppressing excessive adrenal androgen production. Proper GC replacement therapy in 21- and 11 $\beta$ -hydroxylase deficiency ameliorates the noxious effects of oversecreted adrenal androgens, averting further virilization, slowing accelerated growth and bone age advancement to a more normal rate, and allowing a normal onset of puberty. GC treatment also leads to remission of hypertension in 11 $\beta$ - and 17 $\alpha$ -hydroxylase deficiency by diminishing oversecretion of hormonal precursors with MC activity. Excessive GC administration should be avoided since this produces cushingoid facies, growth retardation, and inhibition of epiphyseal maturation. In the enzyme deficiencies impairing MC synthesis, the inclusion of

a salt-retaining steroid in the replacement therapy is required to maintain adequate sodium balance.

Hydrocortisone (cortisol) is most often used; it is the physiologic hormone and does not introduce the complication of adjustment for potency, biologic half-life, or altered profile of steroid action. Oral administration is the preferred and usual mode of treatment; it has conventionally been believed that better suppression of adrenal androgen production is achieved with divided doses, although this has been questioned (297); 10–20 mg/m<sup>2</sup> hydrocortisone divided equally in two daily doses by tablet is adequate for the otherwise healthy child. In non-life-threatening illness or stress, increased dosage of two to three times the maintenance regimen is indicated for a few days. Each family must be given injection kits of hydrocortisone (25 mg for infants, 50 mg for young children, and 100 mg for older patients) for emergency use. In the event of a surgical procedure, a total of 5–10 times the daily maintenance dose (depending on the nature of the operative procedure) may be required over the first 24 h and can then be rapidly tapered.

If there is poor response to hydrocortisone at the standard dose, dosage may be increased to 20–30 mg/m<sup>2</sup>/day, or the regimen may be changed to either one of the hormone analogs, prednisone (17 $\alpha$ ,21-dihydroxypregna-1,4-diene-3,11,20-trione) or dexamethasone (9 $\alpha$ -fluoro-16 $\alpha$ -methylprednisolone). These agents are more potent and are longer acting, although their relative GC and MC effects differ and the smaller amounts used make dosage adjustment more critical. Because of differences in hepatic metabolism and variability in the plasma half-life of 11-oxosteroids, prednisolone (11 $\beta$ -hydroxyprednisone) is found in some patients to be more effective than prednisone in the replacement of cortisol function. Classic 21-hydroxylase patients with salt losing additionally require MC replacement. The cortisol analog (21-acetyloxy)-9 $\alpha$ -fluorohydrocortisone (Florinef; 9 $\alpha$ -FF), is used for its potent MC activity. In an adrenal crisis, a patient unable to ingest medication or take fluids is administered high doses of hydrocortisone intravenously, along with liberal infusions of isotonic saline.

Increasing attention has focused on the role of the RAS in 21-hydroxylase deficiency CAH. Although aldosterone levels may not be deficient in simple virilizing cases, it is well known that PRA is elevated in non-salt-wasting, as well as salt-wasting 21-hydroxylase deficiency (298,299). In spite of this observation, it has not been customary to attempt to correct PRA in the therapeutic management of non-salt-wasting 21-hydroxylase deficiency. Inclusion of a salt-retaining steroid in the steroid regimen for non-salt-wasting patients with elevated PRA was found to improve hormonal control (299). Rösler showed that the PRA in 21-hydroxylase deficiency patients was closely correlated with the ACTH level. Thus, when PRA was normalized by the administration of 9 $\alpha$ -FF, the ACTH level fell and excessive

adrenal androgen secretion diminished. In addition, it was found that the GC dose could often be decreased in these patients and that normalization of PRA often resulted in improved statural growth, a finding borne out in subsequent reports (300).

Steroid RIAs have been useful not only for the initial diagnosis of CAH but also for improved monitoring of hormonal control once therapy has been instituted. Serum 17-OHP and  $\Delta^4$ -A levels provide a sensitive index of biochemical control in steroid 21-hydroxylase deficiency (301,302). In females and prepubertal males, but not in newborn and pubertal males, the serum testosterone level is also a useful index. The combined determinations of PRA, 17-OHP, and serum androgens, as well as the clinical assessment of growth and pubertal status, must all be considered in adjusting the dose of GC and salt-retaining steroid for optimal therapeutic control. Combinations of hydrocortisone and  $9\alpha$ -FF have proved to be highly effective (302).

Measurement of PRA can be used to monitor efficacy of treatment not only in 21-hydroxylase deficiency, but also in other salt-losing forms of CAH (StAR and  $3\beta$ -HSD deficiencies). It is also useful as a therapeutic index in those forms of CAH with MC excess and suppressed PRA (11 $\beta$ -hydroxylase and 17 $\alpha$ -hydroxylase deficiencies). In poor control, PRA is elevated in the salt-losing forms and suppressed in the MC-excess forms.

### 87.7.2 Fertility in Nonclassic 21-Hydroxylase Deficiency

Since the presumptive identification of the first nonclassic patients some 50 years ago, it has been recognized that infertility in women may be reversed during GC therapy (55,303). GC treatment is effective in suppressing adrenal androgen production and, with time, clinical signs of androgen excess show improvement. Given the 9-month life expectancy of established hair follicles, remission of hirsutism generally takes at least 1–2 years. A precise timetable to regression of each clinical sign has yet to be established, but Riddick and Hammond (304) reported that five patients with postmenarchal onset of 21-hydroxylase deficiency resumed regular menses and demonstrated adequate suppression of 17-KS and pregnanetriol within 2 months after beginning therapy with GCs alone. Birnbaum and Rose (303) found that of 18 infertile women with acne and/or facial hirsutism and hormonal criteria consistent with 21-hydroxylase deficiency, five conceived after 2 months, and one patient after 7 months of prednisone treatment alone; four more women conceived within 2 months of the addition of clomiphene to the therapeutic regimen. Hormonal profiles after initiation of therapy were not reported in this study. Oligospermia and subfertility have been reported in men with nonclassic 21-hydroxylase deficiency (305,306) and reversal of infertility with GC treatment has been reported (41,307,308). In a study of response to ACTH

stimulation in a population of men with infertility and idiopathic oligospermia, none of the 50 subjects tested by Ojeifo and colleagues (308) demonstrated a 17-OHP response consistent with the diagnosis of nonclassic 21-hydroxylase deficiency.

**87.7.2.1 Sex Assignment.** Sexual ambiguity at birth characteristic of male or female undervirilization is a common presenting sign of CAH. In these cases, rational and judicious choice of sex assignment is a critical aspect of treatment, since the decision of sex assignment has obvious lifelong implications. Determination of genetic sex by karyotype or buccal smear and the accurate diagnosis of the specific underlying enzymatic defect are essential in assessing a patient's potential for future sexual activity and fertility.

In cases of female undervirilization due to 21- or 11 $\beta$ -hydroxylase deficiency, female sex assignment is appropriate. When medical treatment is begun early in life, the initially large and prominent clitoris shrinks slightly and, as the surrounding structures grow normally, it becomes much less prominent, so that surgery may not be required. When the clitoris is conspicuously enlarged or when the abnormal genitalia interfere with parent–child bonding, surgical revision to correct the appearance of the clitoris should be performed. Definitive vaginoplasty should be performed by an experienced gynecologic or urologic surgeon (309). An early one-stage vaginal and perineal reconstruction has been developed (310) that dispenses with a second-stage procedure.

Because of the normal internal genitalia, gonadal structure and karyotype in these patients, normal puberty, fertility, and childbearing are possible when there is early therapeutic intervention. In view of this potential for normal female sexual development, it is unfortunate when, as a result of a hasty delivery room examination of the virilized external genitalia, affected females are improperly assigned and reared as males.

In cases of male undervirilization due to enzyme deficiencies impairing androgen synthesis, a sex assignment consistent with the genetic sex (i.e. a male sex assignment) is not always optimal. We consider certain physiologic capacities integral to “normal” male sexual development: a capacity for urinating in a standing position in prepuberty and a capacity for sexual intercourse. Virilization of the genitalia in these children is frequently so extremely and irrevocably incomplete that the anatomy precludes normal male functioning. In these patients, relatively normal sexual development as a female and normal, albeit infertile, sexual activity is possible, so that sex assignment as a female may be preferable. Impaired androgen synthesis also limits the synthesis of estrogens; thus, whatever be assignment of sex, administration of sex steroids will usually be required to induce development of appropriate sex characteristics at puberty—either estrogens if the patient is to be reared as a female or androgens if the patient is to be reared as a male.

Because of the wide individual variability in the presentation of ambiguous genitalia, there are no all-inclusive rules for sex assignment of these patients solely based on genetic sex or type of enzyme deficiency.

### 87.7.3 Psychoendocrine Treatment

Psychologists and psychiatrists well acquainted with these endocrine disorders provide a vital component of the treatment regimen, as one of the major goals of therapy is to ensure that gender role, gender behavior, and gender identity are isosexual with the sex of assignment (311,312).

## 87.8 CONGENITAL ADRENAL HYPERPLASIA: PRENATAL DIAGNOSIS AND TREATMENT

The affected, untreated genetic female with classic virilizing CAH (predominantly the result of a 21-hydroxylase defect, but can also be from an 11 $\beta$ -hydroxylase defect) experiences virilization of the external genitalia because of excess androgen production by the fetal adrenals early on in the course of gestation. While the postnatal manifestations of CAH are hormonally controlled, surgical correction has been the effective treatment of the genital malformation present at birth. The potent semisynthetic steroid dexamethasone, which is able to transit the placental barrier without complete metabolic inactivation, has been found to be effective in suppressing fetal adrenal activity in the affected female fetus and to reduce significantly the degree of virilization exhibited at birth when administered to the pregnant mother at low/moderate doses. Prenatal treatment of 21-hydroxylase deficiency has now been utilized for approximately 30 years. In the majority of prenatally treated cases, reduction of the genital defect has obviated the need for surgical correction in infancy, sparing the baby girl the trauma of genital surgical correction and psychological damage from the genital ambiguity.

Specific prenatal treatment protocols for CAH have been developed in conjunction with the increasing capabilities of prenatal diagnosis. The earliest form of prenatal diagnosis was direct hormonal assay of the amniotic fluid for 17-OHP (313). Hormonal levels of 17-OHP are clearly elevated in cases of the severe, salt-wasting form of 21-hydroxylase deficiency CAH. In simple virilizing and nonclassic CAH, however, 17-OHP levels are normal, rendering this hormonal test useless for the diagnosis of CAH in these forms (314). Linkage with HLA permitted presumptive diagnosis in all forms of 21-hydroxylase deficiency CAH by serotyping of cultured fetal cells from the amniotic fluid, when the HLA types of parents and family index case had been determined (315). Molecular analysis, using DNA obtained by amniocentesis or from chorionic villus sampling (CVS), initially relied on the high degree of polymorphism of the HLA loci for

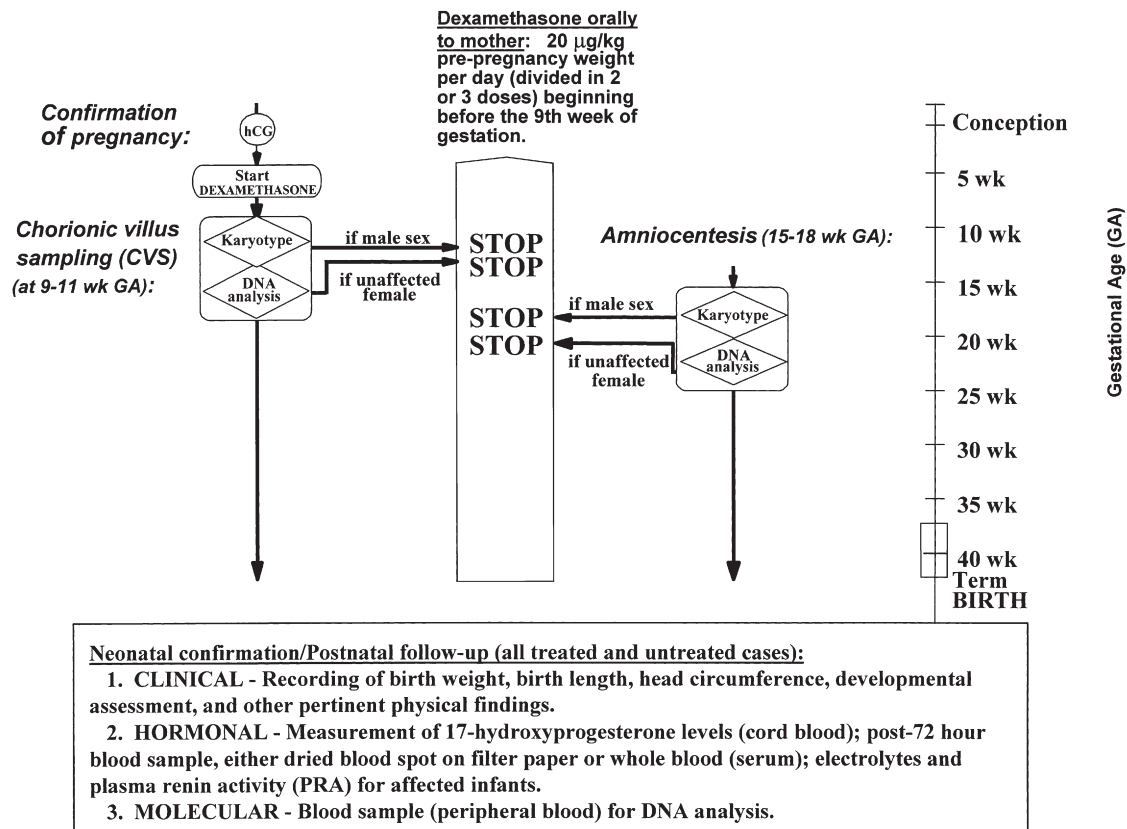

informative DNA results. The accuracy of these results depended on nonrecombination with the marker and 21-hydroxylase loci (316) and thus resulted in many diagnostic errors because of recombination or haplotype sharing between parents. Currently, direct molecular analysis of the 21-hydroxylase locus by allele-specific PCR is used effectively for prenatal diagnosis (134).

The approach we have evolved for prenatal treatment and diagnosis is illustrated in Figure 87-8 (317,318). A couple is determined to be “at risk” for producing CAH-affected offspring usually because of affectation of a prior-born offspring (the index case). In some counseled families the index case may be more distantly related.

Under ideal circumstances, preconceptional genetic evaluations will be undertaken. Basic genetic evaluation consists of 21-hydroxylase genotyping of both parents and the index case. It is of paramount importance that there is the earliest confirmation of pregnancy so that the course of treatment may be started before the ninth week of gestation to prevent virilization of an affected female. The starting treatment regimen is dexamethasone administered orally to the mother at a dose of 20  $\mu$ g/kg maternal prepregnancy weight per day (to a maximum of 1.5 mg) in two or three divided doses. Early start of treatment is essential to anticipate the critical period of genital differentiation in the embryo. Treatment (blind to the status of the fetus) is continued until the diagnostic procedures have been performed and analysis is complete—9–11 weeks for CVS and 15–18 weeks for amniocentesis, plus the time for cell culturing and DNA analysis. Treatment is then stopped in the case of a male fetus (one in two) or unaffected or carrier status of a female fetus (three in eight), but it is continued to term for an affected female fetus (one in eight). Cessation of treatment will be sooner in the case of genetic male fetuses because of the shorter time required for sex chromosome determination.

When properly administered, this regimen of dexamethasone treatment prevents ambiguous genitalia in the affected female. The average Prader score in a large study of prenatally treated fetuses was 1.7, compared with the average score of 3.9 for untreated affected females. In most cases dexamethasone has been well tolerated by the mother, showing no or only minor maternal side effects (317,319,320). In only a few cases has there been frank maternal intolerance of the steroid (321–323). Notably, however, some mothers, even after experiencing side effects, have indicated that they would nonetheless repeat the treatment because of the good result for the affected baby girl (324).

To date, the largest human studies have shown no affected or unaffected fetuses treated interim or to term (317–319,325) for prevention of virilization in CAH to have any congenital malformation related to dexamethasone. In a study by Carlson and colleagues of over 400 pregnancies, 36 mothers carrying affected females were treated full term with dexamethasone. No significant or enduring side effects were noted in fetuses, and

**FIGURE 87-8** Algorithm for prenatal diagnosis and treatment of 21-hydroxylase deficiency.

newborns did not significantly differ in birthweight from untreated newborns (317). In a recent update from the same group, data from almost 600 pregnancies at risk for CAH was analyzed. Of the fetuses 80 were prenatally treated until term and 27 who were male received dexamethasone for a short period. The newborns in the dexamethasone-treated group did not differ in weight, length or head circumference from untreated, unaffected siblings. No significant or enduring side effects were noted in either the mothers or the fetuses. Greater weight gain in treated versus untreated mothers did occur, as well as the presence of striae and edema. Excessive weight gain was lost after birth. No differences were found regarding gestational diabetes or hypertension (326). Data from other groups on long-term follow-up evaluation of CAH-affected and unaffected children exposed to dexamethasone prenatally has shown them to be developing normally and within expected limits, both physically and mentally (317,319,325).

Principles of prenatal diagnosis and treatment for 21-hydroxylase deficiency were also applied to several cases of affected female fetuses with 11 $\beta$ -hydroxylase deficiency (327,328). The treatment was successful, as the newborns were born with normal female external genitalia. Prenatal treatment is therefore safe and effective.

Preimplantation genetic diagnosis (PGD) has been utilized in many monogenic recessive disorders, including CAH. PGD identifies genetic abnormalities in

preimplantation embryos before embryo transfer, so only unaffected embryos established from in vitro fertilization are transferred. There are reports of successful PGD in families whose offspring is at risk for CAH (329), and we know that families are seeking PGD with greater frequency.

The novel approach of noninvasive prenatal diagnosis of CAH is currently being investigated. As discussed, masculinization of the genitalia in a female fetus affected with CAH owing to 21-OHD and 11 $\beta$ -OHD can be treated prenatally with dexamethasone administered to the mother. Because CAH is an autosomal recessive disorder, the risk is 1/4 of the fetus being affected with the disease and 1/8 of the fetus being a female with ambiguous genitalia. Therefore seven of eight pregnancies will receive unnecessary treatment until the sex and the affection status of the fetus are known. Treatment with dexamethasone must begin before the ninth week of gestation, yet chorionic villous sampling can only be done at the 9–11th week, with genotype results available 2–3 weeks later. Noninvasive prenatal diagnosis would eliminate unnecessary treatment and invasive procedures such as CVS and amniocentesis. Lo et al. in 1997 discovered the presence of fetal DNA in the maternal circulation (330). Fetal DNA has been extracted and enriched with high accuracy and yield in fetal Rh factor identification (331) and aneuploidy detection (332,333). Identification of the SRY sequence in maternal blood, performed

in multiple academic centers and by several methods, has also achieved excellent accuracy in several studies (334,335). In noninvasive prenatal diagnosis of CAH, by extracting fetal DNA from the maternal blood at 6–7 weeks gestation, the SRY sequence is to be identified, and if the fetus is female (SRY sequence not identified), DNA analysis of the extracted fetal DNA is to be conducted. There has been only one case reported of prenatal diagnosis in CAH (336); however, studies are underway to further develop this innovative method.

## Biographies

**Dr Maria New** is a Professor of Pediatrics and of Genetics and Genomic Sciences, as well as the Director of the Adrenal Steroid Disorders Program at Mount Sinai School of Medicine in New York City. She is also the Associate Dean for Clinical Research at the Florida International University Herbert Wertheim College of Medicine. Dr New has edited or coedited 12 medical textbooks and published more than 600 peer-reviewed articles. She has conducted pioneering research in the area of congenital adrenal hyperplasia and other adrenal steroid disorders. In addition, Dr New discovered a new form of hypertension, apparent mineralocorticoid excess, which opened a new field of receptor biology. She was also the first to describe dexamethasone-suppressible hyperaldosteronism, another form of low-renin hypertension. In 1999, she reported what may be the first example of a transcription factor defect in humans.

Dr New's contributions have been recognized by her being selected as one of the few pediatricians in the National Academy of Sciences. She has received numerous honors including the Rhone-Poulenc Rorer Clinical Investigator Award from the American Endocrine Society and the 2003 Fred Conrad Koch Award, the highest award given by the American Endocrine Society. In 2010, she received the Van Wyk Prize, the highest award given in pediatric endocrinology.

Dr New received her Bachelors degree from Cornell University and her Doctor of Medicine degree from the University of Pennsylvania, where she was awarded the Distinguished Graduate Award.

**Dr Lekarev** is a Clinical Instructor of Pediatrics and Pediatric Endocrinology at the Mount Sinai School of Medicine. Her areas of interest include congenital adrenal hyperplasia and other adrenal steroid disorders, disorders of sexual development, and noninvasive prenatal diagnosis of genetic disorders. Dr Lekarev graduated cum laude with honors from Barnard College of Columbia University with a bachelor of arts in linguistics. She received her medical degree at the University of Medicine and Dentistry of New Jersey. She completed an internship in pediatrics at the Robert Wood Johnson Medical Center and went on to complete her residency in pediatrics at Tufts-New England Medical Center. Dr Lekarev completed her fellowship in pediatric endocrinology at the Mount Sinai School of Medicine.

**Dr Lin-Su** is a Clinical Associate Professor in Pediatric Endocrinology at Weill Medical College of Cornell University. She is also the Medical Director of CARES Foundation, a non-profit organization committed to improving the lives of families and individuals affected by congenital adrenal hyperplasia (CAH). She is certified in Pediatrics and Pediatric Endocrinology by the American Board of Pediatrics and has received awards from the National Institutes of Health for her rare disease and health research work. Extensively published, her work has appeared in numerous peer-reviewed journals and textbooks. She graduated cum laude with honors from Yale University and received her medical degree at Cornell University Medical College. She completed her pediatric residency and pediatric endocrinology fellowship training at New York Presbyterian Hospital, Cornell.

## Disorders of the Gonads, Genital Tract, and Genitalia

*Joe Leigh Simpson*

Herbert Wertheim College of Medicine, Florida International University, Miami, FL, USA

### 88.1 INTRODUCTION

Disorders of gonadal differentiation resulting from mutant genes are the focus of this chapter. Disorders resulting from abnormalities of sex chromosomes are alluded to only briefly, because they are considered in detail elsewhere in this volume (Chapter 44). Additional clinical aspects of both Mendelian and cytogenetic causes of sex differentiation have been discussed elsewhere by this author (1,2). Disorders of adrenal biosynthesis (21 and 11 $\beta$ -hydroxylase) are discussed in Chapter 87.

### 88.2 46,XX DISORDERS OF SEXUAL DEVELOPMENT

#### 88.2.1 Gonadal and Genital Embryology

Primordial germ cells (PGCs) originate in the endoderm of the yolk sac and migrate to the genital ridge to form the indifferent gonad, which is initially indistinguishable in 46,XY and 46,XX embryos. PGCs migrate from the yolk sac around 28 days (post-conception), reaching the gonadal ridge by 37 days, or 5 days after formation of the genital ridge. Indifferent gonads develop into testes if the embryo—or more specifically the gonadal stroma—is 46,XY. This process begins about 43 days after conception (15 mm crown rump length). Testes become morphologically identifiable 7–8 weeks after conception (9–10 weeks gestational or menstrual weeks).

Sertoli cells are the first cells to become recognizable in testicular differentiation, organizing the surrounding cells into tubules. Both Leydig cells (3) and Sertoli cells (4) differentiate prior to testicular morphogenesis, consistent with their directing gonadal development rather than the converse. These two cells secrete hormones that direct different aspects of male differentiation (Figure 88-1).

Fetal Leydig cells, which are first recognized at 55 days, produce by 63 days an androgen (testosterone) that

stabilizes Wolffian ducts and permits differentiation of the vasa deferentia, epididymides, and seminal vesicles. Following conversion by 5 $\alpha$ -reductase to dihydrotestosterone (DHT), external genitalia are virilized. These actions can be mimicked by the administration of testosterone to female or castrated male mammalian embryos. Fetal Sertoli cells produce anti-Müllerian hormone (AMH, previously called Müllerian inhibitory substance or MIS), a glycoprotein that diffuses locally to cause regression of Müllerian derivatives (uterus and fallopian tubes). AMH also has functions related to gonadal development, given that if AMH is chronically expressed in XX transgenic mice oocytes fail to persist, tubule-like structures develop into gonads, and Müllerian differentiation is abnormal (5). Wolffian differentiation (vasa differentiation, epididymides, seminal vesicles) requires testosterone.

In the absence of a Y chromosome, the indifferent gonad develops into an ovary (6,7), at least embryologically. Transformation into fetal ovaries begins at 50–55 days of embryonic development. By 20 weeks of embryonic life, fetal ovaries contain up to 7 million germ cells, the vast majority undergoing atresia and only 400 actually ovulated as adults. Even in 45,X embryos, oocytes differentiate only to undergo atresia at a rate more rapid than that occurring in normal 46,XX embryos. Thus, genes on the X necessary for normal ovarian development actually control ovarian maintenance. These genes are localized to specific regions of the X, and must be accompanied by various autosomal genes to generate normal ovaries. See Genetic Control of Sex Differentiation below.

Ductal and external genital development occur independent of gonadal differentiation because in the absence of testosterone and AMH, external and internal genitalia develop in female fashion. Absent AMH, Müllerian ducts form the uterus and fallopian tubes, and Wolffian ducts regress. Such changes occur in normal XX embryos, as well as in XY animals that were castrated as embryos prior to testicular differentiation.

**FIGURE 88-1** Schematic diagram illustrating embryonic differentiation in the normal male. (Modified from Simpson, J. L., Elias, S. *Disorders of Sex Differentiation: Gonadal Abnormalities and Hypogonadotropic Hypogonadism*. In *Genetics in Obstetrics and Gynecology*, 3rd ed.; WB Saunders: Philadelphia, 2003.)

## 88.2.2 Genetic Control of Sex Differentiation

Both sex chromosomes (X and Y) and autosomes contain loci that must remain intact for normal sexual development. Knowledge and location of these loci facilitate clinical diagnosis. The initial step in elucidating genetic control distinguishing male from female sex came with recognition that a Y was required for (normal) sexual development.

**88.2.2.1 Genital Ridge.** In the mouse, a number of genes (*Emx2*, *Gata4*, *Lim1*, *Lhx9*) are expressed in the genital ridge. If not present (gene knockout), absence of gonads and internal ducts results. Although expected, perturbations of these genes have not yet been documented in the human genital ridge or in liveborns. However, we shall see that *Wt1* and *Sf-1* knockouts produce such a phenotype and humans with 46,XY disorders of sexual development (46,XY DSD) have shown perturbations of *Wt1* and *Sf1* DSD.

**88.2.2.2 Testicular Development: Loci on Y Chromosome, and Autosomes.** That 46,X,i(Yq) individuals were female in appearance demonstrated nearly 40 years ago that the major testicular determinants (testis-determining factors) were localized to the Y short arm (Yp). Based on (80%) 46,XX male subjects (46,XX sex reversal) arising from interchange of not just the expected homologous pseudoautosomal regions (PARs) of Xp and Yp, but also a greater region encompassing the proximal non-PAR, the pivotal gene on Yp was shown to be *SRY* (sex-determining region Y). In confirmation, 10–15% of sporadic XY sex reversal (female phenotype) show point mutations within

*SRY* (8,9). The *SRY* gene is composed of two open reading frames, 99 and 273 amino acids in length. Based on females with XY gonadal dysgenesis (10,11), the key sequence involves a high-mobility group (HMG) box that has characteristics in common with other DNA-binding and DNA-bending sequences (homeodomains). When XY gonadal dysgenesis is associated with a point mutation in *SRY*, perturbation almost always involves the HMG box. *SRY* is evolutionarily conserved, being present in all male (XY) mammals. *SRY* is expressed before testicular differentiation is manifested (12) and transgenic XX mice with *SRY* predictably show testicular differentiation (13). However, *SRY* alone does not suffice for testicular development nor is it obligatory. This role is played by *SOX9*, located on human 17q24.1–q25.1. *SOX9* has a DNA-binding box and can thus interact with *SRY*.

As already predicted, certain genes (e.g. *NR5A1*) are necessary to establish the genital ridge in anticipation of migration by PGCs. In mice, *Sry* apparently must also be activated by *Gata4*, *Fog2/Nr5a1* and *Wt1*. Murine *Sry* and presumably human *SRY* then upregulates *SOX9*. Upon reaching a given threshold, *SOX9* is believed to sustain itself by a positive regulatory loop involving *FGF9* and *PGD2*. *NR5A1* (SF1) appears to play a synergistic role (14). Haploinsufficiency of the *SOX9* region causes XY sex reversal (male genotype to female phenotype) despite presence of *SRY* (15). Specifically, a region up to 1 Mb upstream of *SOX9* is necessary to produce a male phenotype even if *SOX9* is intact (16). This became evident when deletion (960 kb) of a region 517–1477 kb upstream of

SOX9 led to acampomelic dysplasia and lack of male development in a 46,XY child (17) who had SRY and SOX9. Duplication of SOX9 results in the converse (XX to male phenotype) despite absence of SRY (18). In mice, Qin and Bishop (19) showed definitively that SOX9 is sufficient to direct testicular differentiation in the absence of Sry.

In aggregate, male differentiation must involve derepression by SRY of an otherwise constitutively repressed autosomal testicular-determining autosomal region synonymous with or near SOX9 on 17q24. There exist other less pivotal regions that if deleted impede testicular development in humans. These include 9p24.3 (a region that codes for DMRT) (20–26), 10q26 (a region that encodes), SF1 (NR5A1) for which EMX is a candidate gene (27,28), and 2q33 (29). In addition to duplications of SOX9 and 22q11.2 (30–32), duplication of 1p has resulted in XX sex reversal (XX male) (33). 1p contains Wnt-4, which if overexpressed upregulate DAX1, a dosage-sensitive Xp region (see below). On Xp lies DAX1, a region of significance because it is dosage-sensitive and located on Xp (34). When duplicated, XY individuals undergo sex reversal to female phenotype (the converse of duplication of SOX9 in XX individuals) (34).

**88.2.2.3 Male Internal Ducts.** Testicular Sertoli cells secrete AMH which provided the AMH receptor (AMHR) is intact precludes Müllerian differentiation in males. These processes require several other genes (NR5A1 or SF1, GATA4, WT1, WNT1, SOX8), based on perturbations of these genes resulting in failure of uterine development in females or persistence in 46,XY males. SF1 (NR5A1) especially seems pivotal.

Irrespective of whether Müllerian suppression occurs in 46,XY, Wolffian differentiation can occur if testosterone is produced. Existence of syndromes in which Wolffian derivatives are absent indicates that other genes are required, the best known of which is cystic fibrosis (CF) (CFTR). If CFTR is perturbed, congenital absence of the vas deferens occurs (unilateral CAVD; bilateral CBAVD).

**88.2.2.4 Y Chromosome and Spermatogenesis.** About 15% of azoospermic men have Y-deletions, and about 5–10% of oligospermic men have deletions. Several Y-loci are involved, but their number and interrelationships are still uncertain. The most popular model assumes three loci on Yq: AZFa, the rarest and whose deletion is associated with the absence of spermatogenesis and stem cells; AZFb, whose deletion produces maturational arrest and which corresponds to the locus RNA-binding motif; AZFc, which if deleted is associated with azoospermia and severe oligospermia. AZFc contains the locus DAZ (deleted in azoospermia). Through intracytoplasmic sperm injection, men with DAZ deletions can sire offspring. The Yq deletion is predictably transmitted to all male offspring but none of the females (35).

**88.2.2.5 Gonadoblastoma Y.** Loss of the fluorescent (and presumably contiguous euchromatic nonfluorescent) portion of Yq surprisingly protects against the

germ cell neoplasia that is prevalent in XY women. XY women with deletion of Yq fail to develop neoplasia characteristics of those without deletion. This locus is termed gonadoblastoma Y (GBY) (36,37).

An attractive candidate gene is testis-specific protein Y (TSPY), a multicopy gene (38) upregulated in gonadoblastomas (37) and normally expressed in spermatogonia of normal testes (39).

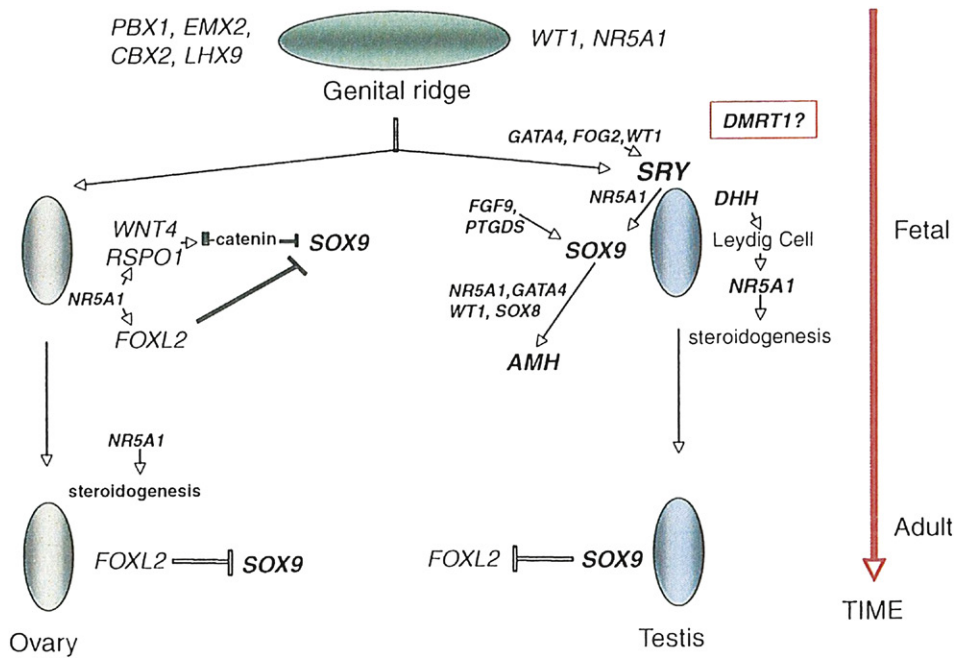

**88.2.2.6 Ovarian Development: Ovarian Maintenance Regions on the X Chromosome.** Pathogenesis of germ cell failure in humans involves as noted increased germ cell attrition. Loci on both the X chromosomes and autosomes are required for normal ovarian differentiation and oogenesis. If two intact X chromosomes are not present, ovarian follicles in 45,X individuals usually degenerate prematurely, if not by birth then at the time of expected adolescence. Genes on the second X chromosome thus could be said to be responsible for ovarian maintenance rather than primary ovarian differentiation. The specific mechanism appears to involve expression of WNT4 and RSPO1, both autosomal loci. If SRY is lacking, SOX9 remains repressed (40), preventing male differentiation. Continued repression of SOX9 is accomplished by FOXL2 (41). FOXL2 is thus essential for ovarian development. Many other genes—X chromosome and autosomal—are, however, necessary for normal ovarian development to proceed normally.

**88.2.2.6.1 Pivotal Regions on the X Short Arm (Xp) and X long Arm (Xq).** Approximately half of 46,X,del(Xp)(p11) individuals show primary amenorrhea and gonadal dysgenesis; other individuals menstruate and usually show breast development. Figure 88-2 shows the author's tabulation of the phenotypes based solely on terminal deletions detectable by karyotype (6 Mb resolution).

In the X short arm, the region of greatest importance involves Xp21–22.1 or 22.2. Women with these deletions usually show complete or premature ovarian failure (POF). Women who have more distal Xp deletions [del(X)(p21.1 to p22.1.22)] and, hence, retain a greater portion of the X menstruate more often than 45,X women; however, many are infertile or have secondary amenorrhea. Women with deletions of Xp are usually short in stature. Given that del(Xp) women may menstruate yet still be short, regions on Xp responsible for ovarian and statural determinants must differ (2,42–46). Both mother and daughter may show the same Xp deletion, for del(X)(p11) as well as for del(X)(p21 or 22) (47–49). Of clinical relevance is that phenotype may vary among relatives in the same family who have the same X-deletion or rearrangement. Interstitial deletions involving Xp11–22 and Xp11.4–22.3 (50,51) have also been reported.

Almost all terminal deletions originating at Xq13 are associated with primary amenorrhea, lack of breast development, and complete ovarian failure (see Figure 88-2) (43,52–54). Xq13 is thus pivotal for ovarian maintenance.

**FIGURE 88-2** The molecular and genetic events in mammalian sex determination and differentiation. (From McElreavey, K., Bashamboo, A. *Genetic Disorders of Sex Differentiation*. Adv. Exp. Med. Biol. 2011, 11, 707, 91–99.)

Del(X)(q21 → 24) individuals menstruate more often than those with more proximal deletions, suggesting that these women might have retained a region containing an ovarian maintenance gene that is deleted in del(X)(q13). (The designation POF2 has been applied to a presumptive locus in the Xq13–21 region, but this label and other similar gene designations for POF may be simplistic.) In terminal Xq deletions at Xq25 or 26, the more common phenotype is not primary amenorrhea but POF (47,53–55). These distal Xq deletions are often familial (56). More distal deletions arise at Xq27 or 28. The “locus” in this more distal deletion has been labeled POF1.

Xq deletions at Xq27 or 28 exert less severe effect on stature than do proximal deletions. Turner stigmata seem no more common than in the general population.

**88.2.2.7 Ovarian Genes on Xp and Xq.** Although gene designations have as noted been assigned to the chromosomal regions on Xp and Xq (POF1, POF2), the actual genes remain unclear. Array CGH copy number variants (CNVs; microdeletions smaller than detectable by conventional karyotype) in women with ovarian failure have also not consistently correlated with that expected if genes were restricted to regions assigned for POF1 and POF2. Knauff et al. (57) found CNVs (262kb resolution deletions) in Xq21.3 to be associated with POF, in a region where PCHCH1X and TGHF2LX are located. However, no deletions were found in other regions considered on the basis of cytogenetic studies to be pivotal. Quilter et al. (58) found that 48% of their cases showed a CNV microduplication or deletion with many X regions involved, whereas Dudding et al. (59) found only a 800-kb duplication at Xq13.3 and a Xp22.3 duplication among 50 POF cases (4%). Aboura et al. (60) reported a statistically significant

association for a 0.217-kb gain on Xq28, but the same gain was found in 5/67 controls. No significant X-deletions were found in 90 POF cases. Discrepancies among these CNV studies are most likely explained by failure to perform the parental array studies that are necessary to exclude paternal transmission of a polymorphic CNV of no likely clinical significance.

Genome-wide linkage analysis has shown association between Xp21.3 (LOD score 3.1) and the age of menopause (61).

Ochalski (62) recently proposed a list of genes having potential relevance to ovarian development and function. Several candidate genes on the X deserve specific comment.

#### 88.2.2.7.1 Xp.

##### 88.2.2.7.1.1 USP9X (Ubiquitin-Specific Protease 9).

This gene maps to Xp11.4 (63) and is expressed in multiple tissues. The *Drosophila* ortholog of USP9X is required for eye development and oogenesis. The role USP9X plays in human gonadal development is still unclear, but its location in the important Xp11.4 region is tantalizing.

##### 88.2.2.7.1.2 Zinc Finger X. Zinc finger X (Zfx) is a

candidate gene for short stature and ovarian failure (64). Mice null for Zfx are small, less viable, less fertile, and characterized by diminished germ cell number in ovaries and testes (65). Their external and internal genitalia are otherwise normal.

##### 88.2.2.7.1.3 Bone Morphogenetic Protein 15. Con-

sidered the strongest candidate gene on Xp is bone morphogenetic protein 15 (BMP15), a member of the transforming growth factor-beta (TGFβ) superfamily. TGF genes direct many developmental pathways through

binding and activating transmembrane serine/threonine kinase receptors. BMP is specifically involved in folliculogenesis and embryonic development, being expressed in gonads.

BMP15 is located on chromosome Xp11.2 and consists of only two exons. Before informative human cases were reported, animal studies had suggested that perturbations of BMP15 could be important in the ovarian failure. Heterozygous Inverdale sheep carrying a mutation in the BMP15 gene shows an increased ovulation rate, with twin and triplet births; primary ovarian failure occurs in ovine homozygotes. BMP15 knockout mutant female mice are subfertile, showing decreased ovulation rates, reduced litter size and decreased number of litters per lifetime (66). In humans, BMP was implicated in POF first by Di Pasquale and coworkers (67) who reported a heterozygous Y235C missense mutation in the second exon of the BMP15 gene in each of two sisters having ovarian failure. The proband had streak gonads and elevated follicle-stimulating hormone (FSH) (80 MIU/mL); the younger sib had one episode of vaginal spotting but otherwise similar. The mother was homozygously normal at this allele, Y235C transmitted from their father. The authors presented in vitro evidence for a dominant-negative mechanism.

#### 88.2.2.7.2 Xq.

**88.2.2.7.2.1 XIST.** Xq13 contains the X-inactivation center and XIST. Loss of germ cells may or may not be the direct result of perturbation of XIST, despite disturbances of X-inactivation per se clearly leading to ovarian failure. The concept of a defined “critical region” necessary for ovarian development receives less attention than in the past, but this does not exclude the region being rich in pivotal genes.

**88.2.2.7.2.2 DIAPH2 (Diaphanous).** This candidate gene lies in the Xq21–24 region. Human DIAPH2 is the homolog of *Drosophila melanogaster* diaphanous (dia). In *Drosophila*, dia is a member of a family of proteins that help establish cell polarity, govern cytokinesis, and reorganize the actin cytoskeleton. In flies, mutations cause sterility in both male and female subjects (68). Xq21/autosome translocation was found to have disrupted the last intron of DIAPH2 in a human patient (69).

**88.2.2.7.2.3 XPNPEP2.** Bione and Toniolo (70) and Prueitt and colleagues (71) found disruption of XPNPEP2 in an Xq/autosome. The proband had POF.

**88.2.2.7.2.4 Angiotensin II (Type 2) (ATZ) Receptor.** Perturbed in a diverse group of disease states, this gene is expressed in fetal tissue. Atretic granulosa cells express the gene in rodents, and thus a plausible relationship could be made between this gene and POF.

Another attractive reason is its location on Xq22–23, a region of known significance (so called POF2). Katsuya (72) studied two families in each of which sibs each had POF; no AT2 mutations were found.

**88.2.2.7.2.5 FMR1.** Fragile X syndrome is a common form of X-linked mental retardation caused by mutation of the FMR1 gene, located on Xq27. The molecular basis involves repetition of the triplet repeat CGG. If more than 200 repeats exist, transcriptional silencing of an RNA-binding protein occurs. This disorder is discussed in detail in Chapter 107. The normal number of CGG repeats is usually 29 or 30. Men or heterozygous women with 55–199 repeats are said to have a permutation (73). During female (but not male) meiosis, the number of triplet repeats may increase (expand). A woman with an FRAXA permutation may have an affected son if the number of CGG repeats on the oocyte of the X she transmits to her male offspring expands during meiosis to greater than 200. That boy will then show mental retardation, characteristic facial features, and large testes (see Chapter 107). Expansion will not occur if there are less than 55 CGG repeats, although the precise threshold remains arguable. Women may also show mental retardation if an X expands, but the phenotype is less severe than in men. About 15–20% of women with an FMR1 premutation (55–100 CGG repeats) develop POF (74).

Schwartz and colleagues (75) found oligomenorrhea in 38% of permutation carriers versus in 6% controls. Allingham-Hawkins and coworkers (76) analyzed 1268 controls, 50 familial POF cases and 244 sporadic POF cases. In this international collaborative survey (76), 63 of 395 premutation carriers (16%) underwent menopause before 40 years of age; the frequency in controls was 0.4%. In a survey of Atlanta women, Sullivan and colleagues (73) found 12.9% of permutation carriers ( $N = 250$ ; >59 repeats) had POF versus 1.3% (2/157) of controls. The number of CGG repeats significantly correlated with the risk of POF but only within selected ranges. Only a slightly increased risk exists with 40–79 repeats, whereas the risk was much higher with 80–99 repeats; there was no further increased risk after >100 repeats. The reason for the plateau is not clear, but consistent with women having the full mutation (>200 CGG) not showing POF (76).

FMRI testing should probably be part of the work-up for POF, and it is so recommended in Europe (77). If oocyte or ovarian slice cryopreservation becomes more feasible, population screening might even be justified for fertility preservation.

Although located in the same region of Xq, FMR1 cannot logically correspond exactly to the region which when deleted causes only ovarian failure in del(Xq). However, On the other hand, terminal deletions at Xq27 (karyotype or array CGH) have been observed in females with fragile X syndrome. This may be the result of skewed X-inactivation such that the sole active X is heterozygous for an FMR1 premutation transmitted from a phenotypically normal but heterozygous mother (78).

**88.2.2.8 Short Stature Homeobox.** Short stature homeobox (SHOX) exists in the PAR1 that involves Xp22 and Yp11.3. SHOX has been proposed as

regulating skeletal growth, reasoning based on short stature existing in Turner syndrome and tall stature in polyploidy X (47,XXY). Consistent with this, SHOX escapes X-inactivation as does all of PAR1. SHOX mutations and deletions have been associated with short stature (79,80), Leri-Weill syndrome (81) and Langer mesomelic dysplasia (82); duplications have also been observed. Tachdjian et al. (83) studied three POF cases known by conventional karyotype to have an Xq deletion, one having del(X)(q21.31) also had an array CGH 620-kb duplication (Xp22.3 → PAR1). Although postulated, a relationship between POF and specifically SHOX seems unlikely. Location of SHOX in the PAR makes it unlikely to have ovarian (or testicular determinants) value. Moreover, we have noted above that cases of 46,X,del(Xp) need not necessarily be short, nor the converse.

**88.2.2.9 Autosomal Ovarian Genes.** Disturbance of many autosomal genes adversely affects normal ovarian development. Some perturbed genes could have a function restricted to oogenesis or ovarian development, whereas in others, ovarian disturbance is only one component of a pleiotropic effect. A host of candidate autosomal genes exist. Genes considered established include FSH receptor (FSHR), luteinizing hormone receptor (LHR), factor in germline alfa (FIGLA) and newborn ovary homeobox (NOBOX). None (save FMR1 and in Finland FSHR) appear to explain more than the occasional case of ovarian failure. See Ovarian Dysgenesis/POF.

### 88.2.3 Nomenclature

The nomenclature used in previous editions to describe clinical disorders of sexual differentiation is time-honored and descriptive. However, some perceive pejorative connotations, and media have often sensationalized affected individuals. For this reason, a revised classification has been proposed (84) (Table 88-1). A problem with this classification is that collapsing heterogeneous disorders into only a few overarching categories unavoidably pools (“lumps”) disparate disorders. Comparisons to older literature containing almost uniquely informative cases also become difficult. In this chapter, we shall attempt to utilize both traditional and more recently “recommended” (84) nomenclature.

**TABLE 88-1 Proposed Revised Nomenclature: DSD**

Traditional	Proposed
Male pseudohermaphroditism	46,XY DSD
Female pseudohermaphroditism	46,XX DSD
True hermaphroditism	Ovotesticular DSD
XX male or XX sex reversal	46,XX testicular DSD
XY female or XY sex reversal	46,XY complete gonadal dysgenesis

### 88.2.4 46,XX Males (XX Sex Reversal)

A systematic review of autosomal causes of ovarian failure will be discussed below, at which time many other genes will receive comment. In the previous section, we reasoned that SRY was the Y-testicular determinant on the basis of analysis of 46,XX (sex-reversed) males. These males have bilateral testes (85,86), and usually have small testes. Androgen deficiency is evident, resembling 47,XXY Klinefelter syndrome. Facial and body hair are decreased, and pubic hair is distributed in the female pattern. About one third have gynecomastia. The penis and scrotum may be small but usually well differentiated (85,86). Wolffian derivatives are normal. Seminiferous tubules are decreased in number and size. Peritubular and interstitial fibrosis is present, Leydig cells are hyperplastic or hypoplastic, and spermatogonia are usually detectable.

In contrast to 47,XXY men, however, virilization may be apparently normal in 46,XX men. Except for sterility, some cases are thus indistinguishable from normal men. Penile differentiation is usually normal; in sporadic cases, genital ambiguity is not uncommon in familial cases bespeaks a different etiologic basis for XX males with genital ambiguity.

Among 46,XX males not having genital ambiguity, 80% show SRY as noted. The cytologic basis is unequal crossing over between Xp and Yp during paternal meiosis. The normal Yp–Xp interchange extends beyond the PAR to include SRY, which is closer to the centromere. The atypical recombination results in SRY becoming translocated from the paternal Y to the paternal X.

In the 20% of nonfamilial XX males lacking SRY, other mechanisms must be postulated. Plausible hypotheses include mosaicism or a mutant autosomal gene (87), the latter seemingly more likely to this author. Indeed, kindreds exist in which there are multiple 46,XX males (88–91) as well as family members having both 46,XX males and 46,XX true hermaphrodites (88,92–94).

### 88.2.5 46,XY Females (XY Sex Reversal) (46,XY Complete Gonadal Dysgenesis)

Gonadal dysgenesis may occur in phenotypic women having apparently normal male (46,XY) chromosomal complements. This phenotype is predictable because loss of testicular tissue before 7–8 weeks would be expected to produce such a phenotype, as originally shown by Jost (6) in rabbits. Indeed, analysis of these women has been pivotal in elucidating the genetic control of sex differentiation. From the clinical perspective, a mutant gene must be systematically excluded.

The various types of XY gonadal dysgenesis are all characterized by structurally normal female external genitalia, vagina, uterus, and fallopian tubes. In at least some cases, the gonads of human XY women were unequivocally ovaries (95–97). This is unequivocally

shown by the extraordinary report of Dumic et al. (97) in which a proband had 46,XY complete gonadal dysgenesis but her mother showed only 46,XY or 45,X cells in lymphocytes, skin fibroblasts and ovary. These cases contrast with the usual XY gonadal dysgenesis secondary sexual development fails to occur at puberty (absent the exceptional case just cited). Height is normal, and in prototypic cases, somatic anomalies are not present. As in 46,XX gonadal dysgenesis without somatic anomalies, FSH and LH are elevated, and estrogens are decreased. In the absence of somatic abnormalities indicative of a syndrome, women with XY gonadal dysgenesis may be indistinguishable from those with XX gonadal dysgenesis on the basis of physical examination.

XY gonadal dysgenesis does contrast, however, with XX gonadal dysgenesis in one very important way. Approximately 20–30% of XY gonadal dysgenesis patients develop a dysgerminoma or gonadoblastoma (98) presumably as a result of presence of the GBY locus (see above). Neoplasia (gonadoblastoma or dysgerminoma) may arise in the first or second decade, necessitating prophylactic gonadal extirpation. Whether this applies to all XY females discussed in this section is unclear, but prudence dictates that one should make this assumption. Laparoscopic removal of gonads and sometimes a gonadoblastoma or dysgerminoma are possible (99,100). Importantly, however, the uterus and fallopian tubes should not be removed because the patient may wish to use her uterus to carry a pregnancy achieved through donor oocytes or donor embryos. Successful pregnancies are documented.

**88.2.5.1 Absence or Mutation in SRY.** Aa alluded to already, deletions or perturbations of SRY precludes testicular differentiation and leads to XY sex reversal. Approximately 10–15% of sporadic XY gonadal dysgenesis cases show perturbations of SRY (8,9). The mutation typically usually involves the HMG box (10,11).

**88.2.5.2 X-Linked XY Gonadal Dysgenesis.** XY gonadal dysgenesis may also segregate in the fashion expected of an X-linked recessive or sex-limited autosomal dominant disorder (1,10,101–104). If on the X, the locus involved appears distinct from DAX1. Contemporary genome-wide molecular studies have not been conducted in order to determine if autosomal regions are perturbed.

**88.2.5.3 DAX1 Duplication.** XY sex reversal may be due to duplication of an X-linked gene initially called dose-sensitive sex reversal region and now DAX1. The locus lies on Xp21. One of 27 “46,XY sex reversal women” studied by Bardoni and colleagues (34) showed duplication of Xp21.2622.1. DAX1 is upregulated by Wnt-4. Overexpression presumably occurred in a case in which a 46,XY female had 1p duplication (33).

**88.2.5.4 MAP3K1.** Pearlman et al. (105) reported mutations in MAP3K1 in two families each showing a range of abnormal sexual phenotypes in XY individuals. Phenotypes included not only XY sex reversal (female)

but also phenotypic males with simple hypospadias. In one family, a splice acceptor mutation (c.634-8T>A) was segregating and in the second missense Gly616Arg. Of 11 sporadic XY females surveyed for MAP3K1 mutations, two missense mutations were found. It was speculated that the disparate phenotypes indicated that MAPK directs the balance between male-determining loci (SOX9 and FGF9) and female-determining loci (WNT4 and CTNNB1, the latter upregulating FOXL2).

**88.2.5.5 CBX2/M33.** An extraordinary 46,XY individual having ovaries (oocytes), uterus and female external genitalia was reported by Biason-Lauber (95). Compound heterozygosity existed for CBX2, a gene located on 17q25.3 and homologous to M33. In mice, Cbx2/M33 suppresses Hox genes during embryogenesis. Given that HOX genes are not typically invoked as pivotal for gonadal differentiation, the relationship between the observed phenotype and mutation is still tenuous. Half of XY mice undergoing M33 knockouts show female phenotype, as did the sole human case.

**88.2.5.6 Desert Hedge Hog.** Desert Hedge Hog is a signaling protein localized in 12q12 → 13. Umehara and coworkers (106) studied a 46,XY phenotypic woman with neuropathy and female external genitalia; it was stated that there was a “blinded vagina with an immature uterus.” A testis was present on one side and a streak gonad on the other. A diagnosis of “partial gonadal dysgenesis” was made, but this author would apply the term mixed gonadal dysgenesis. Irrespective of this, a homozygous mutation was found at the initiating codon of exon 1, resulting in no gene product.

**88.2.5.7 SF1 (NR5A1) Deficiency of Steroidogenic Factor-1 (SF-1) (NR5A1).** Steroidogenic factor-1 (SF-1) plays a potentially pivotal role in the hypothalamic–pituitary–gonadal axis. The Sf-1 gene product is encoded by FTZ1, located on human 9q33. FTZ1 has two zinc finger motif proteins. The first human case of presumptive SF-1 deficiency due to mutant FTZ-1 was reported by Achermann and coworkers (107). A 46,XY phenotypic woman showed primary adrenal failure, female external genitalia, streak gonads and normal Müllerian derivatives responsive to hormones. The proband proved heterozygous for a 2-bp substitution at codon 35 (G35E) in SF-1. The assumption of compound heterozygosity was made, although a second mutation could not be detected; SRY, steroidogenic acute regulatory (StAR) protein, and DAX1 were normal. That the mutated amino acid involved glycine in the last amino acid of the first zinc finger of SF-1 suggests disturbance of a DNA-binding site.

The second XY SF-1 sex reversal case involving SF1 was homozygous for Arg92Gln (108). Two normal family members were heterozygous. A further case (109) had adrenal insufficiency and seemingly normal ovarian differentiation showing that a Y chromosome does not obligatorily prevent ovarian development. Of clinical significance, a uterus is present in genetic males (46,XY)

with SF-1 deficiency, forming the basis for believing that SF-1 regulates repression of AMH. SF-1 heterozygous mutations have been observed in XY sex reversal or genital ambiguity cases who do not show adrenal insufficiency (110a,111a,112a).

**88.2.5.8 GXY Gonadal Dysgenesis and Campomelic Dysplasia (SOX9).** XY gonadal dysgenesis is associated, we have noted, with campomelic dysplasia (CPD) and SOX9. CPD is caused by haploinsufficiency of SOX9 and presents clinically as a de novo autosomal dominant mutation. The perturbation may be missense or nonsense mutations or deletions and sometimes visible chromosomal abnormalities (113). About 75% of XY cases are sex-reversed females. However, perturbations of SOX9 need not manifest solely as XY sex reversal, nor do all SOX9 mutations causing XY sex reversal have characteristic skeletal anomalies (114). (If bowing of long bones—campomelia—is not present, the term acampomelia is applied.) The variable phenotype presumably reflects existence of modifying genes, loss of a contiguous gene or mutations elsewhere in the 1-Mb SOX9 promoter region (115).

**88.2.5.9 XY Gonadal Dysgenesis and Wilms' Tumor Oncogenes (WT1).** Recognition that perturbations of WT-1 (Wilms' tumor oncogene), a gene on 11p13, were relevant to sex differentiation began when the association of nephropathy, genital ambiguity, and Wilms' tumor was observed in a male child. This constellation of features became known as Denys-Drash syndrome (116). Mental retardation, aniridia, and Wilms' tumor were then shown to be associated with deletions of 11p13, the location of the WT1 gene (117). The molecular basis is most often a heterozygous mutation in exons encoding a zinc finger motif (118). The mutant protein is believed to exert a dominant-negative effect given manifestation in heterozygotes.

In Denys-Drash syndrome, phenotypic males show genital ambiguity (male pseudohermaphroditism); however, a few individuals are 46,XY women (sex-reversed). Gonadal development thus ranges from streak gonads through dysgenetic testes to 46,XY ovotesticular DSD (true hermaphroditism) (119). Mueller (118) stated that half the phenotypic females with WT1 mutations were actually 46,XY. The manner by which mutations of WT1 produce genital abnormalities is unclear, but presumably related to WT1 having many isoforms (8) and certain molecular peculiarities. These include alternative translation initiation sites, alternative differential splicing in exon 5 and alternative donor-acceptor sites at the exon 9/intron 9 border. The latter results in differential splicing of the three amino acids lysine (K), serine (S), threonine (T), or KTS (120,121). The ratio of KTS (+) and KTS (–) transcripts differs in testes and ovary (122). This same pathway appears to be involved in Fraiser syndrome (119), characterized by a renal parenchymal disease in addition to XY sex reversal. In Frasier syndrome, the mechanism

of gene action involves an imbalance of KST+ and KST– transcripts (123).

WT1 is believed to act upstream of SRY. In mice, the WT1 null mutation results in failure of either males (46,XY) or females (46,XX) to develop gonads (and kidneys) (124). Both SRY and WT-1 are found in the testes, but WT-1 is expressed earlier. Thus, WT-1 is required upstream of SRY (i.e. before SRY is expressed) (8).

**88.2.5.10 XY Gonadal Dysgenesis and Alpha Thalassemia X Chromosome.** ATX (alpha thalassemia X chromosome) is a member of the DNA helicase family (125,126). Localized to Xq12–q21.31, mutation of ATX causes mental retardation,  $\alpha$ -thalassemia, abnormal facies (e.g. upturned nose, carp-shaped mouth), and male pseudohermaphroditism. The molecular perturbation generally is a truncated protein (127,128). The genital phenotype may be hypospadias or micropenis, or it may extend to sex reversal (female external genitalia) (125–127,129,130). Lack of Müllerian derivatives suggests that AMH was expressed early in embryogenesis prior to when embryonic testes failed to persist.

**88.2.5.11 XY Sex Reversal and Autosomal Deletions (2q, 9p, 10q).** In considering the genetics of sex determination, we have already alluded to several other autosomal regions that deleteriously affect male sex differentiation if deleted. Best known is 9p, deletion of which has on multiple occasions produced XY gonadal dysgenesis (20–26,131). 9p24.3 contains a domain homologous to key sex-determining genes in *Caenorhabditis elegans* (mab3) and *D. melanogaster* (doublesex or dsx). The human locus is dmrt1 (doublesex and mab3-related transcription factor 1). Calvari and colleagues (132) concluded that del(9)(p24.3) was a frequent cause of sry-positive 46,XY gonadal dysgenesis; of 11 deletions, 3 showed complete deletion of one “dmrt1” allele. Raymond and coworkers (133) found far fewer 9p deletions, even when investigating two 9p24.3 domains (dmrt1 and dmrt2). In sequencing 87 unexplained XY sex reversal patients, only 1 mutation was found in dmrt1 and 0 in dmrt2. A later study by the same group found no deletions using a dmrt1 fish probe (134). It was postulated that both dmrt1 and dmrt2 must be deleted to cause XY sex reversal (133). Necessity for two genes implies a quantitative threshold for dmrt gene activity, only below which testicular differentiation is adversely affected. This would imply a variable phenotype, which indeed occurs in del(9) (26).

Slavotinek and coworkers (29) reported sex reversal associated with deletion of 2q33. Waggoner and colleagues (135) reported sex reversal associated with deletion of 10q26, the chromosome on which SF-1 is located.

**88.2.5.12 Leydig Cell Hypoplasia LHR.** In the absence of Leydig cells, 46,XY individuals have female external genitalia, no uterus, and bilateral testes devoid of Leydig cells. Epididymides and vasa deferentia are present, and serum LH is elevated. Affected siblings have been reported and prenatal consanguinity observed. Thus,

autosomal recessive inheritance was accepted long before the LHR gene was localized to 2q. In 46,XY cases, Leydig cells presumably fail to develop because LH cannot exert its normal effect during embryogenesis. Embryonic testes presumably still secrete AMH, explaining the absence of a uterus.

The LHR gene consists of 11 exons and 699 amino acid residues. These exons comprise intracellular domains, intracellular and extracellular loops, transmembrane domains, and extracellular domains. Inactivating mutations lead to complete resistance to LH and XY women, whereas partial resistance leads to men with a small penis or hypospadias (136).

Approximately 12 different LHR mutations have been found in 46,XY women (137). Kremer and coworkers (138) reported two siblings of consanguineous parents having homozygosity for a missense mutation (codon 593). Deletions, point mutations, and stop codons have also been recognized (136,139). Sinha (140) reported homozygous in-frame 27-bp insertion in exon 1 in two 46,XY phenotypic female sibs. Given that in several others this mutation has been present in compound heterozygosity, it is likely to be nonfunctional.

46,XX cases are typically detected in families in which their 46,XY sibs who are female in appearance present with primary amenorrhea.

Of additional interest, activating LHR mutations cause precocious puberty in boys, but activating LHR receptor mutations do not exert the same effect in girls.

**88.2.5.13 Germ Cell Failure in Both Sexes (XY and 46,XX).** In several sibships, both males (46,XY) and females (46,XX) have shown germ cell failure. No other organ systems were affected with regard to differentiation. Affected females show streak gonads, whereas males show germ cell aplasia (Sertoli cell only syndrome). In two families, parents were consanguineous, and in neither were somatic anomalies observed (141,142).

These families demonstrate that a single autosomal gene may be capable of deleteriously affecting germ cell development in both sexes, presumably acting at a site common to early germ cell development (e.g. migration) or to the genital ridge. Several of the genes expressed in the genital ridge (see Genetic Control of Sexual Differentiation) could be candidates. Disturbances involving migrating PGCs are another possibility (See Figure 88-1).

In some families, germ cell absence in both 46,XY and 46,XX sibs coexist with distinctive patterns of somatic anomalies. It is reasonable to assume that these families display a different disorder. Al Awadi and coworkers (143) reported germ cell failure and an unusual form of alopecia. Scalp hair persisted in the midline, but no hair was present on sides (“manelike”). Mikati and colleagues (144) reported germ cell failure, microcephaly, short stature, mental retardation, and unusual facies (e.g. synophrys, abnormal pinnae, micrognathia, and loss of teeth). The sibs reported by Al Awadi and coworkers (143) were Jordanian; those reported by Mikati and

colleagues (144) were Lebanese. In both families, parents were consanguineous.

**88.2.5.14 46,XY Gonadal Regression or Testicular Regression (Agonadia) (46,XY).** In this condition, historically labeled agonadia, gonads are completely absent, external genitalia are abnormal but usually female-like, and no more than rudimentary Müllerian or Wolffian derivatives present. External genitalia usually consist of a phallus about the size of a clitoris, underdeveloped labia majora, and often nearly complete labioscrotal fusion. Less often, external genitalia are nearly female in appearance. Approximately half show somatic anomalies: craniofacial, vertebral, and mental retardation (121).

Given the usually observed 46,XY complement, pathogenic explanations have focused on loss of testes early in embryogenesis. In 46,XY individuals, this must take into account not only absence of gonads (presumptively testes) but also abnormal external genitalia and lack of internal genital ducts. The most frequent hypothesis is transient presence of fetal testes (hence testicular regression), sufficiently long to initiate male differentiation and suppress Müllerian differentiation but not sufficiently long to complete male differentiation. Consistent with this hypothesis, SRY is present in XY gonads.

46,XX cases have been described in which the phenotype seems similar—absent gonads, abnormal external genitalia, rudimentary Müllerian or Wolffian derivatives (145). Invoking testicular regression is obviously not logical in 46,XX cases. One plausible hypothesis is defective connective tissue (field defect). Given existence of both heritable tendencies (146) and frequent coexistence of somatic anomalies, such a hypothesis seems reasonable. This explanation applies also to 46,XY cases having somatic anomalies. Indeed, 46,XY agonadia has been observed in the CHARGE association (147). In one case (148), heterozygous SF-1 mutation was reported.

#### 88.2.5.15 Other Malformation Syndromes.

Table 88-5 lists other malformation syndromes that show XY sex reversal. These syndromes include XY gonadal dysgenesis and ectodermal anomalies (149); XY gonadal dysgenesis in the genital–palato–cardiac (Gardner–Silengo–Wachtel) syndrome (150); and XY gonadal dysgenesis, spastic paraplegia, optic atrophy, and microcephaly (151).

### 88.2.6 DSD Causing 46,XY or 45,X/46,XY Genital Ambiguity (Male Pseudohermaphroditism) (46,XY DSD or Mixed Gonadal Dysgenesis)

If individuals with a Y chromosome have external genitalia that fail to develop as expected for normal males, a variety of disorders could be responsible. The term 46,XY DSD or male pseudohermaphroditism is generally applied. In the disorders discussed in this section, external genitalia are usually sufficiently ambiguous

**TABLE 88-2 Malformation Syndromes in Which Male Pseudohermaphroditism (46,XY DSD) Is One Component**

Syndrome	OMIM Number	Prominent Features	Etiology
Ablepharon-macrostomia	200110	Absent eyelids, eyebrows, eyelashes, external ears; fusion defects of the mouth; ambiguous genitalia; absent or rudimentary nipples; parchment-like skin; delayed development of expressive language	Autosomal recessive
Aniridia–Wilms' tumor association	194070	Moderate to severe mental deficiency, growth deficiency, microcephaly, aniridia, nystagmus, ptosis, blindness, Wilms' tumor, ambiguous genitalia, gonadoblastoma	Chromosomal or autosomal dominant
Antley–Bixter	210750	Craniosynostoses, synostoses, radius, and humerus, Bowing of ulna and femur, arachnodactyly, joint contractures	Autosomal recessive? (P450 oxidoreductase deficiency)
Asplenia, cardiovascular	208530	Hypoplasia or aplasia of the spleen complex cardiac malformations, abnormal lung lobulation, anomalous position and development of the abdominal organs, agenesis of corpus callosum, imperforate anus, ambiguous genitalia, contractures of the lower limb	Autosomal recessive
Beemer	209970	Hydrocephalus, dense bones, cardiac malformation, bulbous nose, broad nasal bridge, ambiguous genitalia	Autosomal recessive
Jacobsen	147791	Trigonocephaly, flat and broad nasal bridge, micrognathia, carp mouth, hypertelorism, low-set ears, severe congenital heart disease, anomalies of limbs, external genitalia	Autosomal dominant or Chromosomal
Denys–Drash	194080	Wilms' tumor, nephropathy, ambiguous genitalia with 46,XY karyotype	Unknown
Fraser	219000	Cryptophthalmia, defect of auricle, hair growth on lateral forehead to lateral eyebrow, hypoplastic nares, mental deficiency, partial cutaneous syndactyly, urogenital malformation	Autosomal recessive
Lethal acrodysgenital dysplasia	270400	Failure to thrive, facial dysmorphism, ambiguous genitalia, syndactyly, postaxial polydactyly, Hirschprung disease, cardiac and renal malformations	Autosomal recessive
Rutledge	270400	Joint contractures, cerebellar hypoplasia, renal hypoplasia, ambiguous genitalia, urologic anomalies, tongue cysts, shortness of limbs, eye abnormalities, heart defects, gallbladder agenesis, ear malformations	Autosomal recessive
SCARF	312830	Skeletal abnormalities, cutis laxa, craniosynostosis, ambiguous genitalia, psychomotor retardation, facial abnormalities	Uncertain
Short rib polydactyly, Majewski-type	263520	Short stature; short limbs; cleft lip and palate; ear anomalies; limb anomalies, including preaxial and postaxial polysyndactyly; narrow thorax; short horizontal ribs; high clavicles; ambiguous genitalia	Autosomal recessive
SLO	270400	Microcephaly, mental retardation, hypotonia, ambiguous genitalia, abnormal facies	Autosomal recessive (deficiency 7-OH cholesterol dehydrogenase)
Trimethadione, teratogenicity	N/A	Mental deficiency, speech disorders, prenatal onset growth deficiency, brachycephaly, midfacial hypoplasia, broad and upturned nose, prominent forehead, eye anomalies, cleft lip and palate, cardiac defects, ambiguous genitalia	Teratogenicity
VATER association	192350	Vertebral, anal, tracheoesophageal, and renal; anomalies, subjects with ambiguous genitalia as part of the cloacal anomalies	Unknown (if valid entity); alleged progestational teratogenicity unproved

to generate confusion concerning the sex of rearing, and, hence, the term is not applied typically to simple hypospadias.

**88.2.6.1 Teratogenic Forms.** If given in sufficiently high doses in the first trimester to a woman pregnant carrying a male fetus, certain drugs would be expected to interfere with male genital development. These include cyproterone acetate, flutamide, and finasteride. The mechanism of action of cyproterone involves blocking the androgen receptor (AR), as does flutamide to a lesser extent. A third drug is finasteride, which inhibits 5 $\alpha$ -reductase. Potential consequences of perturbing these functions are obvious—46,XY DSD or even complete sex reversal. However, case reports apparently do not

exist. Still, these drugs are approved in various countries for treatment of hirsutism or even contraception, so the potential for teratogenic male pseudohermaphroditism exists. Absence of case reports may reflect uncommon exposures in pregnant women or absence of effect due to low-exposure doses.

Controversy persists concerning whether administration of progestins or progesterones during pregnancy can produce hypospadias. This author's opinion is that evidence is considerably against these agents adversely affecting genital development (152,153). Certainly in doses resulting from inadvertent exposure to progestins in hormonal contraception, this is the case.

**88.2.6.2 Mixed or Partial Gonadal Dysgenesis (45,X/46,XY Mosaicism).** A variety of phenotypes are associated with 45,XY/46,XY mosaicism ranging from almost normal men with cryptorchidism or penile hypospadias to those with genital ambiguity to those who are phenotypically normal women (1,154). Based on cohort studies of 45,X/46,XY mosaicism unexpectedly detected in utero (prenatal genetic diagnosis) in unbiased fashion, 90% of cases with this mosaicism are normal males (155). The phenotype of cases ascertained postnatally differs from that of those ascertained prenatally. Differing phenotypes are presumed to reflect differing tissue distributions of the various cell lines, but this is still not unproved. The Y chromosome may be structurally unstable (e.g. dicentric), as a result of which a 45,X line may arise secondarily following loss of a structurally abnormal Y.

**88.2.6.2.1 45,X/46,XY Unambiguous Female External Genitalia.** 45,X/46,XY individuals may be short, have Turner stigmata and thus be clinically indistinguishable from 45,X individuals. Other 45,X/46,XY cases are normal in stature and show no somatic anomalies. As in other types of gonadal dysgenesis, external genitalia, vagina, and Müllerian derivatives remain unstimulated because of the lack of embryonic sex steroids. Breasts fail to develop; pubic and/or axillary hairs are scanty. If breast development occurs in a 45,X/46,XY individual, an estrogen-secreting tumor such as gonadoblastoma or dysgerminoma should be suspected (156). Virilization has been reported and is speculated to be on the basis of gonadotropin stimulation and androgen-producing interstitial cells in streak gonads (157).

Although streak gonads of 45,X/46,XY individuals may be histologically indistinguishable from those of 45,X individuals, gonadoblastomas or dysgerminomas develop in about 15–20% of 45,X/46,XY individuals (98,156). As noted earlier, the GBY locus (GBY chromosome) on Yq predisposes to neoplasia in phenotypic XY women if not deleted by a chromosomal rearrangement. If GBY is deleted, the risk of neoplasia is not apparently increased in XY sex-reversed females (158).

Gonadal extirpation is recommended for all 45,X/46,XY individuals having female external genitalia,

**TABLE 88-4 Mendelian Disorders Associated with Ovarian Failure**

Disorder	OMIM Number	Somatic Features	Ovarian Anomalies	Etiology
Cockayne syndrome	216400	Dwarfism, microcephaly, mental retardation, pigmentary retinopathy senility. Sensitivity to ultraviolet light	Ovarian atrophy and fibrosis	Autosomal recessive and photosensitivity, premature
Martsolf syndrome		Short stature, microbrachycephaly, cataracts, abnormal facies with relative prognathism due to maxillary hypoplasia	"Primary hypogonadism"	Autosomal recessive
Nijmegen syndrome	251260	Chromosomal instability, immunodeficiency, hypersensitivity to ionizing radiation, malignancy	Ovarian failure (primary)	Autosomal recessive (7;14 rearrangement)
Werner syndrome	277700	Short stature, premature senility, skin changes (scleroderma)	Ovarian failure	Autosomal recessive
Rothmund–Thompson syndrome	268400	Skin abnormalities (telangiectasia, erythema, irregular pigmentation), short stature, cataracts, sparse hair, small hands and feet, mental retardation, osteosarcoma	Ovarian failure (primary hypogonadism or delayed puberty)	Autosomal recessive
Carbohydrate-deficient glycoprotein syndrome, type 1 (phosphomannomutase deficiency)		Neurologic abnormalities (e.g., unscheduled eye movements), ataxia, hypotonia/hyporeflexia strokes, joint contractures	Ovarian failure (hypogonadism) (287)	Autosomal recessive
Ataxia telangiectasia	208900	Cerebellar ataxia, multiple telangiectasias (eyes, ears, flexor surface of extremities), immunodeficiency, chromosomal breakage, malignancy, X-ray hypersensitivity	"Complete absence of ovaries," "absence of primary follicles"	Autosomal recessive
Bloom syndrome	210900	Dolichocephaly, growth deficiency, sun-sensitive facial erythema, chromosomal instability (increased sister chromatid exchange), increased malignancy	Ovarian failure	Autosomal recessive

Updated from Simpson, J. L.; Elias, S. *Genetics in Obstetrics and Gynecology*, 3rd ed.; WB Saunders: Philadelphia, 2003.

probably arguably even if GBY is absent. Neoplasia may develop in the first or second decade of life; thus, surgery should not await expected puberty. If breast development and pubarche are present, one should assume a hormone-producing tumor (gonadoblastoma or dysgerminoma) because the expected streak gonads should not be hormone producing. Gonadectomy can usually be accomplished by laparoscopy (99,100). The uterus should be retained because pregnancy may be desired through donor oocytes or donor embryos.

**88.2.6.2.2 45,X/46,XY Ambiguous External Genitalia.** In individuals who have ambiguous external genitalia and a 45,X/46,XY complement, a uterus is usually (90%) present. Many investigators believe that the phenotype is invariably associated with 45,X/46,XY mosaicism, although only 45,X or only 46,XY cells may be demonstrable. The term asymmetric or mixed gonadal dysgenesis is applied to individuals having one streak gonad and one dysgenetic testis.

The presence of a uterus is an important diagnostic sign because that organ is absent in almost all genetic (Mendelian) forms of male pseudohermaphroditism (46,XY DSD) (see later). If an individual has ambiguous external genitalia, bilateral testes, and a uterus, it is reasonable to infer that individual actually has 45,X/46,XY mosaicism, irrespective of whether both cell lines can be demonstrated cytogenetically.

**88.2.6.2.3 45,X/46,XY with Nearly Normal Male External Genitalia.** 45,X/46,XY mosaicism may be detected in individuals with nearly normal male external genitalia. Given 90% of 45,X/46,XY fetuses ascertained at amniocentesis having a normal male phenotype at birth (159), this is the most common phenotype for this mosaicism. That 45,X/46,XY neonates with genital ambiguity are recognized more often simply reflects biases of ascertainment.

45,X/46,XY individuals having almost normal male external genitalia do not seem to develop neoplasia

**TABLE 88-5 The Spectrum of 46,XY Sex Reversal (XY Females)**

XY gonadal dysgenesis without somatic anomalies

– P450 oxidoreductase (POR) deficiency
– 3 $\beta$ -OI dehydrogenase/3 $\beta$ -hydroxysteroid dehydrogenase deficiency

as often as do 45,X/46,XY individuals with female or frankly ambiguous genitalia. Gonadal extirpation need not be necessary if a male sex of rearing is chosen, for gonads can be assessed periodically by ultrasound or palpation if within the scrotum (98).

**88.2.6.3 Genital Ambiguity or Sex Reversal Multiple Malformation Syndromes.** Genital ambiguity is a component of many multiple malformation syndromes (160), some of which have known enzymatic defects [e.g. Smith–Lemli–Opitz (SLO) syndrome (161) and Antley–Bixler syndrome (18a)]. Among the more common are the Meckel–Gruber syndrome (162), SLO (161) syndrome, brachioskeletal–genital syndrome (163), esophageal–facial–genital syndrome, and genitopalatocardiac syndrome (150) (Gardner–Silengo–Wachtel). These disorders are usually autosomal recessive or X-linked recessive (Table 88-2). The many other syndromes are associated only with cryptorchidism nonambiguous hypospadias (164) will not be discussed here.

In SLO syndrome, the mutant gene has disturbed conversion of 7-hydroxycholesterol to cholesterol (165,166). The most common molecular perturbation is a defect in exon-intronic splicing. 46,XY individuals show genital abnormalities (hypospadias or male

pseudohermaphroditism). In Ontario, the incidence was estimated at one per 22,700 among individuals of European ancestry (167). A broad phenotypic spectrum exists (19), and traditionally two clinical types have been differentiated. In type I, simple hypospadias is most common, whereas in type II, external genitalia may be female (sex reversal) (161). The feasibility of postnatal as well as prenatal treatment with a high-cholesterol diet is being explored. Given its low molecular weight, cholesterol crosses the placenta readily. During pregnancy, maternal serum estriol is typically very low to nondetectable (168), making detection during maternal serum analyte screening feasible. Presence of the novel compounds dehydro-estriol and dehydropregnanetriol in maternal urine also indicates a SLO fetus, because in normal pregnancies these compounds are undetectable (169).

Puffenberger et al. (170) reported TSPY-like (TSPYL) 1 mutations in XY males with sudden infant death, testicular dysgenesis, and genital ambiguity; TSPYL is involved in nucleosome assembly. 46,XX cases do not show sexual abnormalities.

In genitopalatocardiac (Gardner–Silengo–Wachtel) syndrome, 46,XY individuals show phenotypic variability, not only in external genitalia but also in gonads (150). Complete sex reversal can occur in 46,XY individuals, who may have ovaries. See Simpson (44) for further discussion.

**88.2.6.4 Disorders of Androgen Synthesis (Testosterone Biosynthetic Defects).** 46,XY DSD may result from deficiencies of various adrenal or gonadal enzymes: 3 $\beta$ -ol-dehydrogenase, the bifunctional enzyme 17 $\alpha$ -hydroxylase/17,20 desmolase, 17-ketosteroid reductase, and the enzymes necessary to convert cholesterol to pregnenolone (congenital adrenal lipid hyperplasia) (Figure 88-3). The common pathogenesis involves low testosterone, specifically levels inadequate to virilize external genitalia. Deficiencies of 21- or 11 $\beta$ -hydroxylase, the most common causes of female pseudohermaphroditism, do not cause male pseudohermaphroditism; males (46,XY) deficient of these enzyme in fact lead to precocious masculinization.

Adrenal biosynthetic defects should be suspected whenever levels of testosterone or its metabolites are decreased. Diagnosis may be difficult during infancy because neonatal testosterone levels are physiologically low. Provocative tests (e.g. human chorionic gonadotropin (hCG) stimulation) may be necessary.

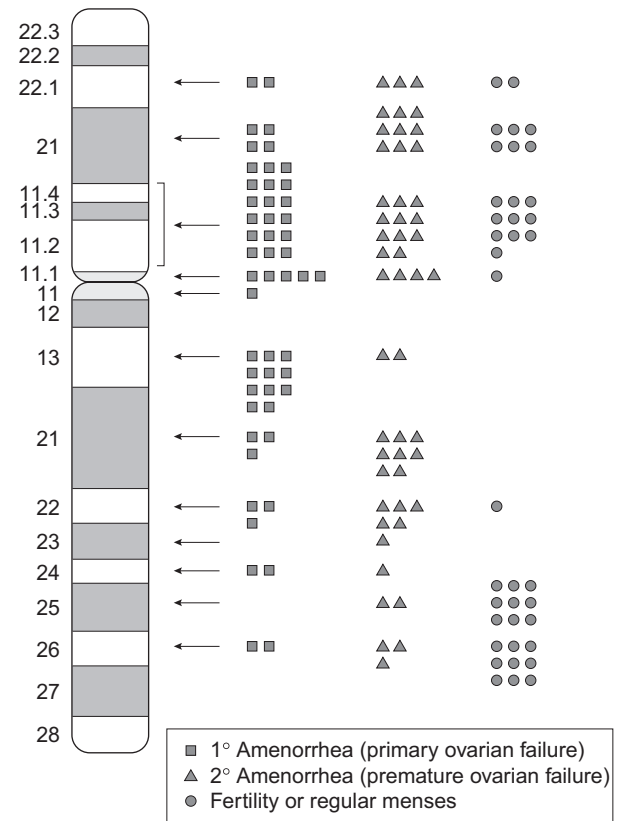

In a European cohort of 98 families with 46,XY DSD in which the proband had low testosterone (171), Morel et al. found molecular perturbations in 35 cases for HSD17 $\beta$ 3, 28 for HSD3 $\beta$ 2, 15 for StAR, 5 for CYP11A, 10 for CYP17, and 5 for POR. In only three cases could a molecular explanation not be found, one with 17 $\beta$ 3 deficiency and two with adrenal lipid hyperplasia. Genetic consequences of mutations involving each of these genes will be discussed below.

**88.2.6.4.1 Congenital Adrenal Lipoid Hyperplasia due to Deficiency of StAR.** In this autosomal recessive disorder (congenital adrenal lipoid hyperplasia), external genitalia are ambiguous or female like (see Chapter 87). Sodium wasting is severe, and adrenals are characterized by foamy appearing cells filled with cholesterol (172,173). Hyperpigmentation is observed, and respiratory distress common (25%) in neonates. Cholesterol accumulation has long been assumed to reflect inability of cholesterol to be converted to pregnenolone (see Figure 88-3). Levels of C18, C19, and C21 steroids are almost undetectable in plasma and urine. If targeted molecular diagnosis cannot be made, prenatal genetic diagnosis may still be possible on the basis of decreased levels of certain hormones in amniotic fluid (174).

Congenital adrenal lipoid hyperplasia in humans has usually proved to be the result of perturbation of the gene encoding StAR protein. The adjective “acute” reflects ability to respond rapidly (“acutely”) to corticotropin stimulation, specifically by producing a 30-kD mitochondrial protein in adrenal cells. The StAR protein facilitates entry of cholesterol into mitochondria, needed to accomplish the above function. Because StAR delivers precursors for cholesterol side chain cleavage, its perturbation has obvious downstream consequences on hormone action in gonads and adrenals. Salt wasting is severe. Mapped to 8p11.2, StAR spans 8kb and consists of seven exons (175). Many reported cases are of Japanese and Korean descent. In these populations, the mutant allele is most often (20%) a stop codon: Gln258X. In Arabs, the mutation is likely to be Arg182Leu. Different mutations have been found in other ethnic groups. Founder effects are presumably operative in these different ethnic groups (175). In Palestinians, del 201–202CT is the common explanation (88a).

**88.2.6.4.2 Congenital Adrenal Lipoid Hyperplasia due to P450scc Deficiency (CYP11A).** Congenital adrenal lipoid hyperplasia has been found in infants lacking a perturbation of StAR or SF-1. The defect here involves deficiency of P450scc, required for enzymatic steps by which cholesterol is cleaved to generate pregnenolone (Figure 88-3). Presumptive CYP11A deficiency with genital abnormalities was first found in a heterozygous mutation and of uncertain but plausible significance (93a,176a). Compound heterozygosity was later shown in two affected infants (93a,177a). Unlike StAR mutations, adrenal problems are not observed (salt wasting).

**88.2.6.4.3 Deficiency of 3 $\beta$ -Hydroxysteroid Dehydrogenase (3 $\beta$ -ol-Dehydrogenase Deficiency) (HSD3 $\beta$ 2).** In this enzyme deficiency, synthesis of both androgens and estrogens is decreased (see Figure 88-3). The major androgen produced is dihydroepiandrosterone (DHEA). A relatively weaker androgen than testosterone, DHEA alone is not capable of adequately virilizing the male fetus; thus, genital ambiguity occurs. The phallus is small, the urethral opening proximal on the penis, and labioscrotal fusion incomplete. Testes and Wolffian

**FIGURE 88-3** Schematic diagram of the X chromosome showing ovarian function as a function of nonmosaic terminal deletion based on pooled data. In familial aggregates, all affected cases are included because their phenotypes are not always concordant. In some cases, patients are described as having POF, but no information is provided on fertility; in the absence of explicit information, it is assumed no pregnancy has occurred. In some younger patients (e.g. >14 years but <20–25 years), there has been little opportunity to demonstrate pregnancy, nor is there assurance regular menses will continue. Nonetheless, they are designated as having “regular menses/fertility.” (Data from Simpson, J. L.; Rajkovic, A. *Ovarian Differentiation and Gonadal Failure*. Am. J. Med. Genet. 1999, 89, 186–200.)

ducts differentiate normally. The diagnosis is usually established in neonates on the basis of disproportionately increased serum DHEA following ACTH stimulation. In addition to genital abnormalities, 3 $\beta$ -ol-dehydrogenase deficiency is associated with severe sodium wasting. This is predictable, given that both aldosterone and cortisol are decreased.

Of the five 3 $\beta$ -hydroxysteroid dehydrogenase (3 $\beta$ -HSD) genes, only type II is expressed in adrenal and gonads. External genitalia of males with type II 3 $\beta$ -HSD deficiency are thus incompletely developed. Mutations are scattered among the four exons, most commonly aggregated in the fourth exon (Figure 88-4) (178,179).

Like 46,XY cases, 46,XX individuals with this enzyme deficiency also show genital ambiguity with virilization due to elevated DHEA and androstenediol. Those androgens are relatively weaker than testosterone but nonetheless sufficiently potent to virilize.

**FIGURE 88-5** Diagram of the 3 $\beta$ -hydroxysteroid dehydrogenase type II (HSD3B2) gene with selected mutations that result in 3 $\beta$ -HSD deficiency. The numbered solid boxes indicate the exons. Missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the enzyme and then the three-letter abbreviation for the substituted amino acid. X indicates a nonsense (stop) mutation. Mutations with less than 1% 3 $\beta$ -HSD activity are indicated below the gene and cause salt loss. Missense and splicing mutations, indicated above the genes, result in 2–4.7% enzymatic activity and are associated with the non-salt-losing phenotype. (Data from Grumbach, M. L.; Leuan, A. H.; Conte, F. A. *Disorders of Sex Differentiation*. In Williams' Textbook of Endocrinology, 10th ed.; WB Saunders: Philadelphia, 2003; pp 842–1002.)

**FIGURE 88-6** Diagram of selected mutations in the CYP17 gene (17 $\alpha$ -hydroxylase/17,20-lyase deficiency). The exons are the numbered black boxes. Missense mutations causing amino acid substitutions in the enzyme are indicated by the three-letter abbreviation for the wild-type amino acid, followed by the amino acid number in the enzyme and the three-letter abbreviation for the substituted amino acid. X indicates a nonsense (stop) mutation. All these mutations cause 17 $\alpha$ -hydroxylase deficiency. Missense mutations at codons 347 and 358 (indicated by the box) have been associated with "isolated" 17,20-lyase deficiency. (Data from Grumbach, M. L.; Leuan, A. H.; Conte, F. A. *Disorders of Sex Differentiation*. In Williams' Textbook of Endocrinology, 10th ed.; WB Saunders: Philadelphia, 2003; pp 842–1002.)

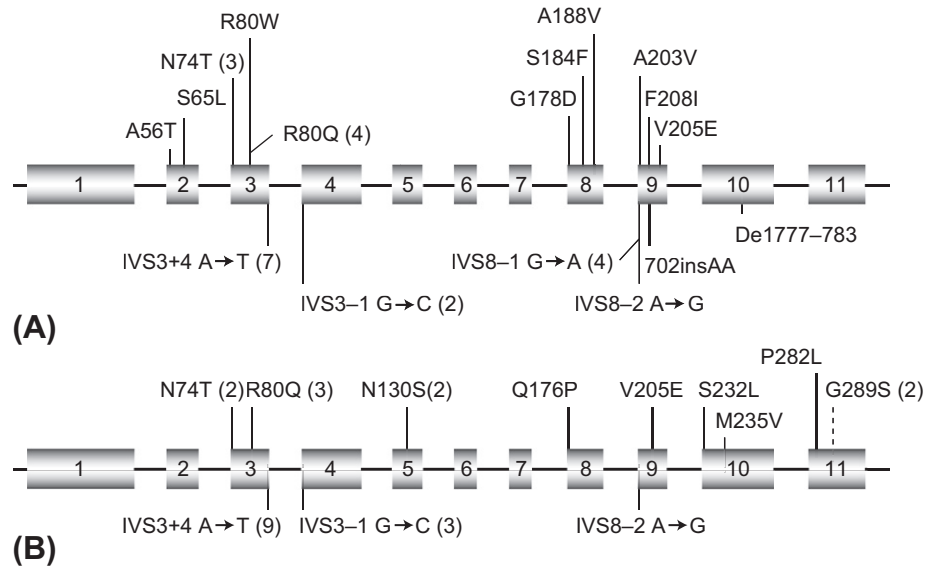

17-ketosteroid reductase, also called 17- $\beta$ -hydroxysteroid dehydrogenase or 17- $\beta$ -ol dehydrogenase (see Chapter 87). There are five 17- $\beta$ -HSD isozymes; deficiency due to HSD17 $\beta$ 3 mutations is causative in this condition. This enzyme reaction is reversible, the multiple designations connoting both oxidative and reductive steps.

Plasma testosterone is usually decreased, whereas androstenedione and DHEA are increased. Affected men show ambiguous or female-like external genitalia, bilateral testes, and Wolffian derivatives, but no Müllerian derivatives. Breast development may or may not be present, apparently depending upon the estrogen to testosterone ratio. Pubertal virilization may be greater than in other enzyme deficiencies, and sometimes gynecomastia is not even evident (191). This is considered the result of androstendione being converted to testosterone by 17- $\beta$ -HSD enzymes other than the 17- $\beta$ -HSD3 (HSD3) enzyme typically utilized. HSD3 deficiency shares with

5 $\alpha$ -reductase deficiency the characteristic of virilization at puberty. Inacio et al. (192a) reported that 3 of 11 cases in a Brazilian cohort chose female to male sex reversal at puberty.

Located on chromosome 9q22, 17HSD3 or HSD3 consists of 11 exons (Figure 88-6). The gene is micro-somal rather than mitochondrial, consistent with its action involving gonads rather than adrenals. Molecular perturbations typically involve single amino acid substitutions (193,194), especially exon 3. Also frequent are disruptions of the splice junction involving intron 3 and mutations in exons 8, 9 and 10. However, mutations encompass all exons (see Figure 88-6).

Among 87 cases reported in 2001, Simard and coworkers (179,195) tabulated 18 missense, 2 frameshift, and 4 splice junction mutations. Most missense mutations have no residual activity, but this is not true for the most common single mutation, a Arg80Gln or R80Q missense mutation

**FIGURE 88-7** Representation of the HSD17B3 mutations identified as of 2003 in homozygotes from 32 families (A) and compound heterozygotes from 14 families (B) suffering from Type III 17 $\beta$ -HSD/17-KSR deficiency. The location of the neutral polymorphism G2895 in the HSD17B3 gene is represented by a broken line. The number in parenthesis indicates the number of families in which a specific mutation has been found. (Data from Simard, J.; Moisan, A. M.; Michel, L. C.; et al. Males with 17 $\beta$ -Hydroxysteroid Dehydrogenase Deficiency. *Endocrinol.* 2003, 13, 195–200.)

in Gaza Arabs (196,197). This mutation, in exon 3, reduces enzyme activity to 20% of normal (179,193,195). The phallus is typically bound by chordee, and only 4–8 cm long. Gynecomastia is common. R80Q has also been found in Portuguese, Spanish, Dutch, and Brazilian patients, said to be consistent with its introduction by the Phoenicians.

46,XX women with mutations at both alleles are asymptomatic (195), consistent with the 17- $\beta$ -HSD3 expression being limited to the testes.

#### 88.2.6.4.7 Deficiency of 5 $\alpha$ -Reductase (SRDA1).

Genetic men may show ambiguous external genitalia at birth but at puberty undergo virilization like normal men. They demonstrate phallic enlargement, increased facial hair, muscular hypertrophy, and voice deepening but no breast development. External genitalia consist of a phallus that resembles a clitoris more than a penis, and a perineal urethral orifice. Usually, there is a separate, blindly ending perineal orifice that resembles a vagina (pseudovagina) (Figure 88-10).

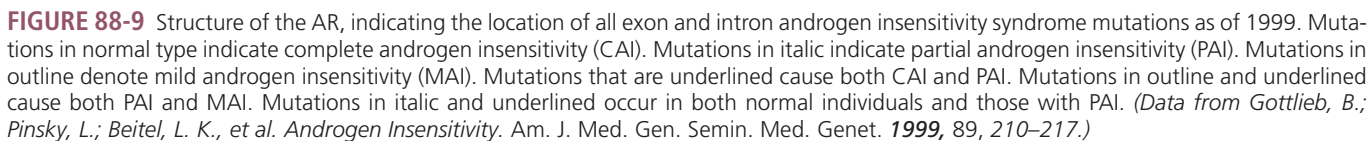

Once called pseudovaginal perineoscrotal hypospadias (PPSH), this disorder was shown in 1971 to be inherited in autosomal recessive fashion (198,199). The responsible enzyme was later shown to be 5 $\alpha$ -reductase (192,200,201), which converts testosterone (T) to DHT. That intracellular 5 $\alpha$ -reductase deficiency results in the PPSH phenotype is consistent with virilization of the external genitalia during embryogenesis requiring only DHT; Wolffian differentiation requires only testosterone. By contrast, pubertal virilization can be accomplished without DHT.

Two 5 $\alpha$ -reductase (SRD5) genes exist. Type I (SRD5A1) is located on chromosome 5; type II (SRD5A2) is located on 2p23. Only type II is expressed in gonads; thus, deficiency of only this product causes

**FIGURE 88-8** Photograph of a 46,XY individual with complete androgen insensitivity. (From Simpson, J. L. *Male Hermaphroditism: Genetics and Clinical Delineation*. Hum. Genet. 1978, 44, 1–49.)

male pseudohermaphroditism. SRD5A2 consists of five exons (202). Missense mutations are common (203), and different ethnic groups typically show different mutations. These are scattered among the five exons, presumably reflecting founder effects (Figure 88-11). Within a given ethnic group, a sentinel mutation is usually observed, typically homozygous and presumably

46,XX women homozygous for SRD5A1 mutations are fertile and show normal ovarian function (207). Breast development is normal. Limb and pubic hair may be reduced, and menarche delayed.

**Syndrome.** In these forms of DSD, testosterone is produced but cellular response and androgen action are lacking. The result is that 46,XY individuals develop phenotypically as females. In complete androgen insensitivity syndrome (CAIS; complete testicular feminization), 46,XY individuals show bilateral testes, female external genitalia a blindly ending vagina, and no Müllerian derivatives (Figure 88-7). The incidence is one per 10,000–20,000. Clinical findings are predictable, given that the underlying pathogenesis is known to involve inability to respond to testosterone. Testosterone levels are in the range expected of 46,XY males. Testes synthesize estrogens in unimpeded fashion, their action not counterbalanced as usual in males by functionally active testosterone. Affected individuals manifest breast development and pubertal feminization. AMH is concurrently synthesized

**FIGURE 88-10** Photograph of a 46,XY individual with incomplete (partial) androgen insensitivity. (From Jones, H. W. Jr.; Park, I. J. *A Classification of Special Problems in Sex Differentiation*. Birth Defects Orig. Artic. Ser. 1971, 7 (6), 113–121.)

normally as predicted by Sertoli cells. The body likewise responds appropriately to AMH, as a result of which there is no uterus. LH is disproportionally increased, presumably reflecting hypothalamic unresponsiveness to testosterone.

In CAIS, some affected individuals may show excellent breast development, an often overemphasized description in textbooks (see [Figure 88-7](#)). Actually, most patients are similar in appearance to women in the general population. Breasts contain normal ductal and glandular tissue, but areole are often pale and underdeveloped. Pubic hair and axillary hair (terminal) are usually sparse (e.g. only vellus hair); scalp hair is normal. Presence of some pubic and axillary hair is usually less common than some axillary hair. This should not dissuade one from the diagnosis of CAIS. The vagina terminates blindly, foreshortened but still usually adequate for coitus. Occasionally, the vagina is only 1–2 cm long or represented merely by a dimple. Use of progressive dilators or even surgery to create a neovagina may be necessary. Neither uterus nor fallopian tubes are ordinarily present, but fibromuscular remnants, rudimentary fallopian tubes, or rarely, even a rudimentary uterus may persist.

Testes are usually normal in size. They may be located in the abdomen, inguinal canal, labia, or anywhere along the path of embryonic testicular descent. If present in the inguinal canal, testes may produce inguinal hernias. Height is slightly increased compared with normal women, but unremarkable compared to 46,XY males. In a Brazilian cohort (25 subjects) (208), adult heights ranged from  $-1.35$  to  $0.59$  SD using normal male standards, i.e. taller than 46,XX females and shorter than normal 46,XY males.

**FIGURE 88-11** Photographs of the external genitalia of an individual with PPSH. At puberty, phallic enlargement occurred and breast development did not. Individuals with this phenotype have  $5\alpha$ -reductase deficiency. (From Opitz, J. M.; Simpson, J. L.; Sarto, G. E.; et al. *Pseudovaginal Perineoscrotal Hypospadias*. Clin. Genet. 1972, 3, 1–26.)

The frequency of gonadal neoplasia is increased due to intra-abdominal location of testes, but before 25–30 years of age, the risk of malignancy is low. Orchiectomy is not necessarily indicated prior to spontaneous pubertal feminization. If herniorrhaphy is required before puberty, however, most surgeons perform orchiectomy simultaneously. Laparoscopy is preferable for removing inguinal testes, but open laparotomy is required for retroperitoneal testes. There may also be some psychological benefits to prepubertal orchiectomies. Benign tubular adenomas (Pick adenomas) are common in postpubertal patients, probably stimulated by increased LH secretion.

Some individuals with androgen insensitivity show clitoral enlargement and labioscrotal fusion; the term incomplete or partial androgen insensitivity (PAIS) (incomplete testicular feminization) is then applied. An even milder end of the spectrum consists of men manifesting only gynecomastia or only oligospermia/azoospermia (mild androgen insensitivity syndrome or MAIS). Complete, partial, and mild androgen insensitivity are all inherited in an X-linked recessive fashion and are due to different mutations of the same AR gene located on the X long arm.

**88.2.7.2 Partial Androgen Insensitivity and Mild Androgen Insensitivity.** At puberty, certain 46,XY individuals with androgen insensitivity feminize (i.e. breast development), but their external genitalia are characterized by phallic enlargement and partial labioscrotal fusion ([Figure 88-9](#)). Defined as partial or incomplete androgen insensitivity (PAIS) (or incomplete testicular feminization), the phenotype shares many features with CAIS: bilateral testes with Leydig cell hyperplasia, absence of Müllerian derivatives, pubertal breast development, lack of pubertal virilization, normal (male)

plasma testosterone, and failure to respond to androgen. Of historical note, PAIS encompasses several entities once considered to be distinct, erstwhile syndromes reported by Lubs and colleagues (209), Gilbert-Dreyfus and coworkers. Differences between these entities reflect molecular heterogeneity (164,210–212). However, family members with the same mutation have shown different sex of rearing have also been reported (213).

PAIS must be excluded before a male sex of rearing can be assigned because ability to respond to exogenous androgens is necessary. Identifying or excluding a specific molecular perturbation can be especially useful if the molecular defect in a relative is already known.

**88.2.7.3 Molecular Studies in CAIS and PAIS.** Perturbation of the AR gene located on Xq11 is responsible for the phenotypes described (CAIS and PAIS). As an X-linked recessive condition that is genetically lethal, one third of all cases would be predicted to be new (sporadic) mutations. Indeed, 8 of 30 (30%) patients studied by Hiort and coworkers (214) were the result of a new mutation. A few heterozygous women show decreased pubic hair and delayed puberty.

The gene is approximately 90,000bp long but codes for fewer than 2000 amino acids. There are eight exons (Figure 88-8). Exon 1 confers regulatory function. The DNA-binding domain of amino acids 552–616 is encoded by exon 2 and part of exon 3. The latter part of exon 3 and part of exon 4 encode bipartite nuclear localization (617–636 amino acids). The C-terminal region of 250 amino acids extends over exons 4–8 and constitutes the androgen-binding domain (211). The gene contains two regions of homopolymeric amino acid “repeats” of varying size: one polyglutamine (9–36 amino acids) and the other polyglycine (10–31 amino acids). Many different mutations have been reported (210,215), tabulated in a registry maintained at McGill University (e-mail: [mc33@musica.mcgill.ca](mailto:mc33@musica.mcgill.ca) or Website: <http://www.mcgill.ca and rogenb>).

Mutations can be found in most cases of CAIS, and in about 75% of PAIS (208). Exon 1 encompasses half of the AR gene, but has the fewest recognized mutations (10%). More mutations have been found in exons 2 and 3 (the DNA-binding domain). The phenotype may be either CAI or PAI. The most common sites of mutation lie in exons 5–8, the androgen-binding domain. Large deletions and mutations resulting in premature termination (stop codon) predictably cause CAIS (215,216). However, most mutations are missense mutations, and these may produce CAIS, PAIS, or MAIS (see below) in seemingly random fashion. Presumably, some point mutations are compatible with production of limited quantities of functional AR, although the receptor may be unstable or characterized by poor binding (216). That a given mutation may be associated with either PAIS or MAIS (12) could suggest modifying genes.

**88.2.7.4 Mild Androgen Insensitivity Syndrome.** In MAIS, phenotypic expression is usually limited to

impaired spermatogenesis. Gynecomastia, impotence, and poor virilization may also occur (217–219). Molecular/phenotypic correlation is imprecise, the same mutation being observed in either MAIS or PAIS (220).

### 88.2.8 Ovotesticular DSD (True Hermaphroditism)

In 46,XY, ovotesticular DSD cases have both ovarian and testicular tissues, and genital ambiguity is typical. This disorder probably accounts for fewer than 5% of all DSD cases, the exception occurring in South Africa where approximately half of all DSD cases (221) have this condition. Almost all cases in Southern Africa are black.

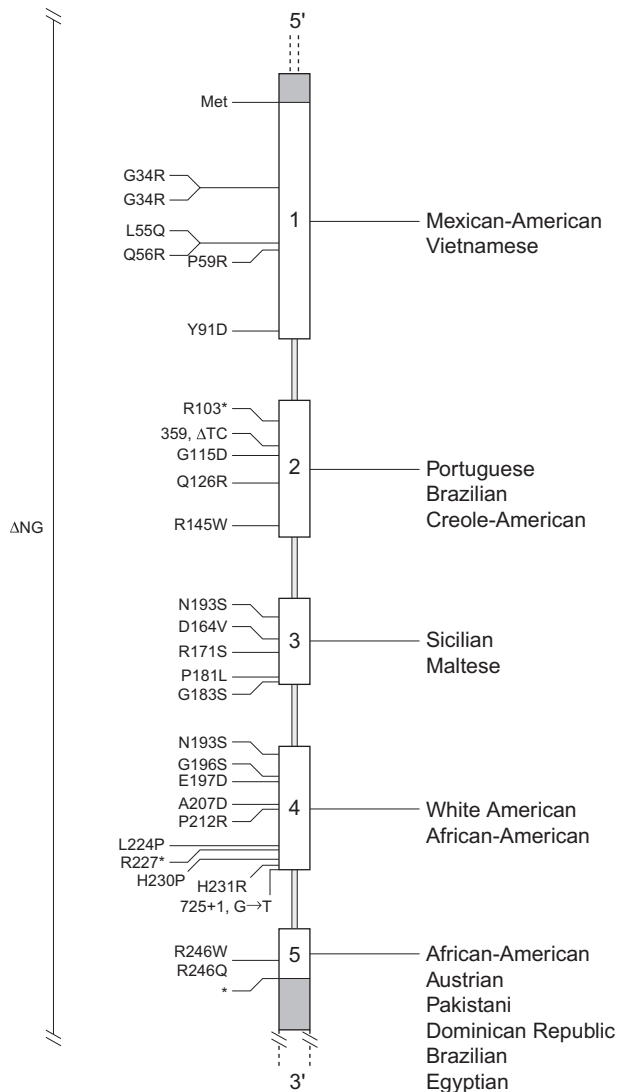

Most cases have a 46,XX chromosomal complement; however, 46,XX/46,XY, 46/XY, 46,XX/47,XXY and other complements exist (222–224).

Gonads may exist as a separate ovary and a separate testis or, more often, one or more ovotestes (222). Phenotype logically should reflect chromosomal constitution in mosaic (or chimeric) cases (224), but this has actually never been proved. Irrespective of this, it will suffice here to generalize concerning the overall phenotype of true hermaphrodites.

**88.2.8.1 Phenotype.** Before the era of routine medical intervention, two thirds of cases were raised as boys (1). Wiersma found that of 125 cases in South Africa reported in 2010, no patient showed normal male or female external genitalia (225). All except two were raised as males. Only 9 of 125 showed separate urethral and vaginal openings. Paradoxically, breast development was typical at puberty, even with predominantly male external genitalia. This may have reflected atrophy of testicular tissue due to intra-abdominal location.

As noted, gonads may consist of two ovotestes: one ovary and one contralateral testis or one ovotestis and a contralateral ovary or testis. Gonadal tissue may be located in the ovarian, inguinal, or labioscrotal regions. A testis or an ovotestis is more likely to be present on the right than on the left. Spermatozoa are rarely present (226); however, ostensibly normal oocytes may exist even in ovotestes. Gonads were palpable in only 59 of the 125 South African cases of Wiersma et al. (221,225) and of these 59 only 17 bilateral. In 66 cases, gonads were in the pelvis. Ovotestes are the predominant gonadal form in South Africa and these were almost always pelvic in location in the series of Wiersma and their tissue distribution was typically bipolar (ovarian cranial and testicular caudal), albeit with interdigitation. In 89% of ovotestes studied by Wiersma, a mantle of ovarian tissue surrounded a core containing stroma and intermingled ovarian and testicular tissue. The clinical significance of gonadal intermingling is that extirpating gonadal tissue of a single type is not simple surgically.

Van Niekerk, whose elegant book in 1974 analyzed a presumably different South African cohort, reported

**FIGURE 88-12** Mutations in the steroid 5 $\alpha$ -reductase 2 gene and protein. A schematic diagram of the 5 $\alpha$ -reductase gene is shown in the middle. On the left are the location of 28 different mutations, and the predominant ethnic groups on the right.  $\Delta$ NG (far left) represents the deletion of the gene in the New Guinea cohort. (Data from Wilson, J. D.; Griffin, J. E.; Russell, D. W. *Steroid 5 $\alpha$ -Reductase 2 Deficiency*. *Endocr. Rev.* 1993, 14, 577–593.)

at the time that the greater the proportion of testicular tissue in an ovotestis, the greater the likelihood of gonadal descent. In 80% of his cases, the testicular and ovarian components of ovotestes were juxtaposed end to end (Figure 88-12) (227), seemingly different from the recent experience of Wiersma. Van Niekerk collected cases from the region surrounding Pretoria, whereas Wiersma (221,225) is active in Durban. Thus, different tribal ancestry may exist. Van Niekerk noted that ovotestis may be detectable by inspection or palpation; testicular tissue is softer and darker than ovarian tissue. Ultrasound or magnetic resonance imaging (MRI) is now obligatory if the undesired portion of an ovotestis is to be extirpated.

Gonadal neoplasia and breast carcinoma have been reported (98,156,224). Gonadal neoplasia may reflect risks associated with intra-abdominal location of testicular tissue. This is consistent with data of Kuhnle and coworkers (228), who estimated that neoplasia arises in 25% of 46,XY cases but in only 3% of 46,XX cases. The preponderance of gonads existing in the form of ovotestes in South Africa is less pronounced elsewhere. Vilain (229) stated that the distribution worldwide is 34% ovotestes/ovary, 29% ovotestes/ovotestes and 25% ovary/testes.

A uterus is usually (90%) present based on cases reported worldwide and based on Van Niekerk's sample (227). Sometimes, the uterus is bicornuate or unicornuate (224). However, in his South African series, Wiersma reported that only 73 of 125 had a "uterine structure." Absence of a uterine horn usually indicates ipsilateral testis or ovotestis. The fimbriated end of the fallopian tube is often occluded ipsilateral to an ovotestis. Squamous metaplasia of the endocervix may occur (227). Menstruation is common and may be manifested as cyclic hematuria. Presence of a uterus in true hermaphroditism is diagnostically useful, particularly in the rare 46,XY case. Of individuals with genital ambiguity having a Y chromosome, only 46,XY hermaphrodites and 45,X/46,XY mosaics have a uterus.

Approximately a dozen true hermaphrodites have become pregnant (230,231), usually (but not always) after removal of testicular tissue. Excluding a single 46,XX/46,XY case (232a), all pregnant individuals have been 46,XX. Their offspring seem no more likely to be abnormal than in the general population, although Kuhnle and colleagues (223) stated that all offspring had been boys.

Diagnosis is typically made when genital ambiguity is observed and only after male and female pseudohermaphroditism are excluded. If a female sex of rearing has been chosen, extensive surgery may or may not be necessary. If a male sex of rearing is chosen, genital reconstruction and selective gonadal extirpation are invariably indicated.

**88.2.8.2 Etiology.** 46,XX/46,XY true hermaphroditism is rare and usually caused by chimerism. The presumptive explanation is chimerism, the presence in a single individual of two or more cell lines by definition each derived from different zygotes. Some 46,XY cases may also be unrecognized chimeras (144). 46,XX/47,XXY individuals are probably more likely to have resulted from nondisjunction or anaphase lag.

In 46,XX true hermaphrodites, possible explanations include translocation during paternal meiosis of SRY from the Y to an X; translocation of SRY from the Y to an autosome; or activation (depression) of autosomal genes. The former can be excluded as uncommon because very few 46,XX cases receive DNA sequences from their father's Y (233). Rarity of X–Y interchange in true hermaphrodites contrasts with its frequent occurrence in

46,XX men, 80% of whom show SRY as a result of such an interchange. A few 46,XX ovotesticular cases do show a mutant SRY, and somatic mutation can result in gonadal mosaicism associated with true hermaphroditism (234).

Autosomal genes seem to be a more likely explanation for 46,XX true hermaphroditism. This hypothesis is supported by existence of families characterized by either multiple siblings with XX true hermaphroditism or families in which both 46,XX males and 46,XX true hermaphrodites occur in the same kindred. (For references, see prior section on 46,XX Males (XX Sex Reversal)). In these kindreds, the 46,XX men usually show genital ambiguity, unlike the typical 46,XX male who shows normal male external genitalia. Familial XX true hermaphrodites seem more likely to be characterized by bilateral ovotestes and absence of the uterus than nonfamilial true hermaphroditism (224); both gonads in familial true hermaphroditism tend to be morphologically similar and ovotestes. This suggests a central basis for gonadal perturbation (224). Given that differing gonadal composition per side logically should more likely be the result of chimerism. Derepression of a normally dormant autosomal gene conferring male differentiation could provide an explanation for unscheduled (testicular) gonadal development in 46,XX individuals. We have already observed instructive cases resulting in 46,XX sex reversal (female genotype to male phenotype) in which duplication of SOX9 has not been well studied in true hermaphrodites that causes 46,XX sex reversal in the absence of SRY.

### 88.2.9 46,XX Ovarian Dysgenesis/POF

Turner syndrome and monosomy X are discussed in detail elsewhere in this volume (Chapter 44). In this chapter, we have also alluded to the pathogenesis of germ cell failure in monosomy X and X-deletions. Here we shall consider mutant autosomal genes causing ovarian dysgenesis in 46,XX individuals (Table 88-3). The archetypal form of “XX gonadal dysgenesis” is characterized by streak gonads not associated with somatic anomalies. Inheritance has long been accepted as autosomal recessive (235). Affected individuals are normal in stature (103) and Turner stigmata are absent. However, “XX gonadal dysgenesis” is very heterogeneous, and this diagnosis will increasingly become more specific. At present, however, only about 10–20% of cases have a precise diagnosis. To a large extent, this reflects limited diagnostic evaluation, in particular failure to perform molecular studies or any evaluation beyond routine cytogenetics.

Of clinical relevance is frequent variable expressivity. In many families, one sibling has had bilateral streak gonads, whereas another ovarian hypoplasia yet not streak gonads per se (1,235–237). Any mutant gene responsible for “XX gonadal dysgenesis” that is capable of variable expression may thus be responsible for isolated cases of “POF.”

**88.2.9.1 FSH  $\beta$ .** FSH is composed of a unique  $\beta$  subunit and an  $\alpha$  subunit shared in common with thyroid-stimulating hormone, LH, and hCG. Cellular action requires a G-protein (GP) FSHR, the gene for which is present on chromosome 2.

Mutations in FSH- $\beta$  are rare, but reported. Two affected women showed neither thelarche nor the menarche. Matthews and colleagues (238) described a homozygous 2-bp deletion (GT) in exon 3 at codon 61. Layman and coworkers (239) reported a compound heterozygote: one allele was characterized by a deletion in exon 3, codon 61, whereas the other was a missense mutation in exon 3, codon 51.

**88.2.9.2 Inactivating FSHR.** FSHR mutations are common in Finland but rare elsewhere. In a landmark study, Aittomaki and colleagues (236,237) meticulously searched Finnish hospitals and cytogenetic laboratories to identify 75 women having 46,XX primary or secondary amenorrhea, based on serum FSH > 40 MIU/mL. The gene was first localized to chromosome 2p and then a missense mutation in exon 7 of FSHR (C566T or Ala566 Val) found in six families (236,237). This mutation lies in the extracellular portion of this GP. Women heterozygous for the mutation did not show decreased fertility.

The Ala566 Val mutation is uncommon outside Finland. No mutations in FSHR were found in North American women having either 46,XX hypergonadotropic hypogonadism (239) or POF (240). Similar findings were reported in 46,XX POF or primary amenorrhea cases from Germany (241), Brazil (242), and Mexico (243). Compound heterozygosity for FSHR mutations has been observed, namely genotypes Ile-160Thr/Arg573Cys and Asp224Val/Leu602Val (244).

**88.2.9.3 Inactivating LHR.** Most reported LHR mutations are 46,XY and have resulted in XY sex reversal (137) (page XXX). However, LHR mutations in 46,XX women cause the phenotype XX gonadal dysgenesis.

All 46,XX cases with LHR mutations have been recognized in sibships ascertained through affected 46,XY siblings, who presented with Leydig cell hypoplasia and XY sex reversal. LHR is 75 kD in length and consists of 17 exons. Located on 2p near the locus for FSHR, the first 10 exons in LHR are extracellular, the 11th transmembrane and the last 6 intracellular. Most mutations have been detected in the transmembrane domain of this GPR.

Latronico and coworkers (136) reported a 22-year-old woman who presented with primary amenorrhea due to an LHR mutation. In that family, three 46,XY sibs also had the same homozygous C544X mutation, which resulted in a truncated protein consisting of five rather than seven transmembrane domains. The 46,XX sib had breast development but only a single episode of menstrual bleeding at age 20 years; LH was 37 MIU/mL, and FSH was 9 MIU/mL. The mutation reduced the signal transduction activity of the LHR gene. In another 46,XX case, Latronico and colleagues (136) observed secondary amenorrhea; LH and

FSH were 10 and 9 MIU/mL, respectively. A homozygous mutation for Ala593Pro was found.

Other 46,XX women with LHR mutations may show oligomenorrhea. Ovulation does not occur, even though gametogenesis proceeds until the preovulatory stage. This is consistent with mouse knockout models (245).

Interestingly, activating LH receptor mutations have little effect in women despite activating LHR mutations causing precocious puberty in males (137).

**88.2.9.4 Inhibin A.** INHs are heterodimeric glycoproteins that consist of an  $\alpha$  subunit and either of two  $\beta$  subunits ( $B_A$  or  $B_B$ ), producing  $INH\alpha$  or  $INH\beta$ , respectively. These genes exert negative feedback inhibition on FSH. INHs are opposed by activins, which enhance FSH secretion. Given that INH is synthesized by granulosa cells, it is not surprising that in POF serum INH is low given FSH concomitantly elevated. Elevated FSH and low INH thus indicate reproductive aging. Perturbation of INHs could plausibly cause ovarian failure.

Several studies have claimed shown associations between POF and a specific INHA missense mutations or polymorphisms—G769A (Ala57Thr) (246,247). Studying patients from New Zealand, Shelling and colleagues (248) found G769A in 3 of 43 POF patients (7%) versus only 1 of 150 normal controls (0.7%). However, the mother of one of the three G769A individuals had the same perturbation and was clinically normal. Marozzi and coworkers (249) found G769A in 7 of 157 Italian POF individuals, 3 of 12 primary amenorrhea cases, and 0 of 36 early menopausal (40–45 years) women. Familial POF cases were relatively more likely to have G769A than sporadic cases. Dixit and colleagues (250) found G769A in 9 of 80 Indian POF cases; no mutations in  $INH\beta$  or  $INB\beta$  were found. Also studying an Indian cohort, Prakash et al. (251) found the variant in heterozygous form in 3 of 30 cases of primary amenorrhea, 3 of 20 with secondary amenorrhea, and 2 of 50 controls. Thus, normal individuals have had the G769A transition, and in fact individuals with G769A may be normal even if another G769A family member has POF; thus, G769A does not obligatorily confer ovarian failure at least in heterozygotes. More recent reports by Shelling and his group (252) have expanded rationale for function but not defined mutation(s) unequivocally causing POF (247,253–255).

**88.2.9.5  $17\alpha$ -Hydroxylase/17,20 Desmolase Deficiency (CYP17).** In discussing 46,XY DSD, we described 46,XY individuals with a CYP17 defect. Less commonly, 46,XX individuals have been reported with a CYP17 defect, presenting with primary amenorrhea or POF (256). Thus, deficiency of  $17\alpha$ -hydroxylase/17,20 desmolase should be considered an uncommon cause of 46,XX hypergonadotropic hypogonadism. Hypertension may coexist but less commonly than in 46,XY cases. Ovaries in affected cases are hypoplastic and sometimes have a streak-like appearance. Oocytes appear incapable of reaching diameters of more than 2.5 mm (190).

Stimulation with exogenous gonadotropins can produce oocytes capable of fertilization in vitro (257).

**88.2.9.6 Aromatase Mutations (CYP19) (46,XX) (CYP19).** Conversion of androgens ( $\Delta^4$ -androstenedione) to estrogens (estrone) requires cytochrome P450 aromatase (CYP19), an enzyme that is the gene product of a 40-kb gene located on chromosome 15q21.1 (241a). The gene consists of 10 exons.

46,XX aromatase deficiency may present with primary amenorrhea in phenotypic women. Ito and coworkers (258) reported an aromatase mutation (CYP19) in a 46,XX 18-year-old Japanese woman having primary amenorrhea and cystic ovaries. The patient was a compound heterozygote, having two different point mutations in exon 10. The mutant protein had no activity. Conte and colleagues (110) also reported aromatase deficiency in a 46,XX woman presenting with primary amenorrhea, elevated gonadotropins, and ovarian cysts. Compound heterozygosity for two different exon 10 mutations was found. One was a C1303T transition leading to cysteine rather than arginine, whereas the other was a G1310A transition leading to tyrosine rather than cysteine.

A different phenotype was reported by Mullis and coworkers (259). Clitoral enlargement occurred at puberty, and there was no breast development. Multiple ovarian follicular cysts were present. FSH was elevated; estrone and estradiol were decreased. Estrogen and progesterone therapy resulted in a growth spurt, decreased FSH, decreased androstenedione and testosterone, breast development, menarche, and decreased follicular cysts. Compound heterozygosity was found.

Placental aromatase deficiency can cause 46,XX DSD (female pseudohermaphroditism), as a result of POR deficiency.

Aromatase deficiency in 46,XY males leads to increased testosterone, macrorchidism and atherosclerosis but not 46,XY DSD (260).

**88.2.9.7 Progesterone Receptor Membrane Component 1.** This X-linked gene was interrogated in 67 POF cases, finding 1 heterozygous mutation (H165R) (261). The change occurred in a domain necessary for nontranscriptional regulation of cytochrome P450, potentially a functional effect.

**88.2.9.8 FOXL2/Blepharophimosis–Ptosis–Epicanthus.** In Genetic Control of Sex Differentiation, we discussed the pivotal role FOXL2 plays in ovarian development. Encoded on 3q21–24, the protein of FOXL2 must be expressed in order to maintain suppression of SRY and allow ovarian differentiation to proceed. FOXL2 and other forkhead DNA-binding proteins are crucial in signal induction. Blepharophimosis–ptosis–epicanthus (BPE) syndrome is an autosomal dominant malformation syndrome in which FOXL2 is perturbed. One of the two types of this syndrome (type II) is characterized by POF (262). FOXL2 is expressed in eyelids and ovaries (263). In four families, FOXL2 mutations

co-segregated with BPE and POF. Nonsense mutations reported include stop codons as well as a 17-bp duplication that resulted in a frameshift and, hence, truncated protein.

In the absence of somatic features, FOXL2 mutations are uncommon explanations for POF. De Baere and colleagues (264) found no FOXL2 mutations in 30 POF patients lacking eyelid abnormalities; Harris and coworkers (265) found two mutations among 70 cases. In 1 of the 70 cases of Slovenian origin, a deletion (A221–A230) removed 10 of the 14 alanines in the poly A tail (266). In a patient of New Zealand origin, a missense mutation (Tyr258Asp) was found.

**88.2.9.9 Newborn Ovary Homeobox.** NOBOX is a homeobox gene, an example of the genes that bind DNA and function as transcription factors to direct differentiation. NOBOX (NOBOX gene) encodes a homeobox transcriptional regulator. NOBOX is oocyte specific, expressed from the primordial follicle through metaphase II. Female null mice (knockout) show ovarian failure, whereas males are normal. One earlier study failed to show NOBOX perturbations in 30 Japanese women (63), but our group found two novel missense mutations (Arg355His and Arg360Gln) among 96 Caucasian POF cases (267) and Arg355His was present in a conserved region. Electrophoretic mobility shift arrays using Arg355His DNA showed disrupted binding of the NOBOX homeodomain to DNA, thus capacity for exerting a dominant-negative effect.

**88.2.9.10 Growth Differentiation Factor 9.** GDF9 is a member of the TGF $\beta$  family, like BMP15 (which is also called GDF9b). GDF9 can form dimers with BMP15. Expressed in oocytes, GDF9 is an attractive candidate gene. Various heterozygous mutations have been detected in some European and Asian samples (135,255,268,269), but not in others (270–272). A deleterious heterozygous change requires a dominant-negative effect, plausibly given dimerization and presumably analogous to deleterious effect of BMP15 mutations. If missense mutations like a hydrophobic amino acid replacing a hydrophilic amino acid are causative, GDF9 perturbations could account for substantial number (1–4%) of POF cases.

**88.2.9.11 BMPR1B.** Homozygous deletion (del 359–366) of BMPR1B, another autosomal TGF $\beta$  superfamily gene, was reported by Demirhan et al. (273) in a 16-year-old female with ovarian failure and acromesomelic chondrodystrophy. Although murine knockouts for this gene are infertile (274), heterozygous mutations of the BMPR1B homolog in sheep can lead to increased fertility (gain of function) (275). This is similar to the phenotype experienced by sheep heterozygous for BMP15 (FecX) mutations (276).

**88.2.9.12 Factor in Germline Alfa.** This gene on 2p13.3 is a germ cell-specific basic helix-loop-helix transcription factor. It regulates expression of zona pellucida genes. FIGLA is expressed in the embryonal ovary and in FIGLA knockout mice. Primordial follicles are either

not formed or all lost soon after birth. Zhao et al. (277) studied 100 Han Chinese with POF and found 3 variants in 4 women. A missense mutation (A49) was found in 2 cases: a 15–36 deletion (p.G6fsX66) in one that results in a frameshift and dysfunctional haploinsufficiency and a 419–421 deletion (140 del N). Functional studies of the latter (140delN) demonstrated that FIGLA binding to the TCF3 helix-loop-helix was impeded. This gene is attractive for interrogation in other ethnic groups.

**88.2.9.13 POU5F1.** This transcription factor gene located on 6p21.31 is significantly downregulated in NOBOX knockout mice, which lack ovaries. Thus, POU5F1 becomes a potential candidate gene, a downstream target of NOBOX. Wang et al. (278) sequenced 175 Chinese POF cases and found one non-synonymous variant (Pro13Thr), a heterozygous hydrophobic to hydrophilic substitution.

**88.2.9.14 PTH-Responsive B1.** PTHB1 was reported to be associated with POF in a small study (24 cases and 24 controls) (279). The use of a gene association of genome-wide association study (GWAS) formal for a sample size this small is considered inadequate. Sequencing data are awaited.

**88.2.9.15 ADAMTS.** Located on 5q14.1 → q15, this gene was found to be associated with POG in the discovery set of a GWAS performed on 99 Dutch POF cases and 181 controls (280). However, the finding was not confirmed in the replication set. Given this considerably underpowered GWAS, conclusions concerning the role this transcription factor plays in POF remain uncertain.

**88.2.9.16 Myotonic Dystrophy (CTG<sup>N</sup>).** Myotonic dystrophy is an autosomal dominant disorder characterized by muscle wasting (e.g. head, neck, extremities), frontal balding, cataracts, and male hypogonadism (80%) attributable to testicular atrophy (see Chapter 122). Female hypogonadism is much less common than male hypogonadism if increased at all. Despite frequent citations in texts, ovarian failure in myotonic dystrophy appears not well documented.

Pathogenesis of myotonic dystrophy involves nucleotide expansion of CTG repeats in the 3' untranslated region of the causative gene, which is located on chromosome 19. Normally, 5–27 CTG repeats are present. Heterozygotes usually have at least 50 repeats; severely affected individuals show 600 or more. As in FRAXA (FMR1) (see below), response to ovulation induction regimes is poor. Sermon and colleagues (281) reported fewer embryos per cycle than in standard assisted reproductive technologies (ARTs); thus, pregnancy rates in preimplantation genetic diagnosis were thought to be decreased. However, more recent reports show better results (232), perhaps indistinguishable from the general population of infertile women undergoing ART.

**88.2.9.17 Galactosemia.** Discussed in Chapter 93, galactosemia is due to galactose 1-phosphate uridyl transferase (GALT) deficiency. Ovarian failure may occur. Kaufman and coworkers (282) reported POF in 12 of 18 galactosemic women, and Waggoner and colleagues (283)

reported ovarian failure in 8 of 47 (17%) women with galactosemia. Pathogenesis presumably involves galactose toxicity after birth, given that elevated fetal levels of toxic metabolites should be cleared rapidly in utero by maternal enzymes. Consistent with this idea, a neonate with galactosemia showed normal ovarian histology (112).

There remains little reason or evidence to believe that galactosemic heterozygotes show POF. Not all homozygotes for human galactosemia are abnormal, nor are transgenic mice in which GALT is inactivated (knockout) (284).

**88.2.9.18 Carbohydrate-Deficient Glycoprotein (Phosphomannomutase Deficiency, PMM2).** In type 1 carbohydrate-deficient glycoprotein deficiency, mannose 6 phosphate cannot be converted to mannose 1 phosphate. This lipid-linked mannose-containing oligosaccharide necessary for secretory glycoproteins cannot be synthesized. The gene is located on 16p13, and the usual molecular perturbation is a missense mutation (285). In addition to characteristic neurological abnormalities (286), ovarian failure is frequent. FSH is elevated, secondary sexual development fails to occur, and ovaries lack follicular activity (287,288).

**88.2.9.19 Autoimmune Regulation/Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dystrophy.** The AIRE gene located on 21q22.3 is responsible for the condition titled by the physical features listed above. In addition to the abnormalities defined by the appellation, other findings include alopecia, vitiligo, keratopathy, malabsorption, hepatitis, and mucocutaneous candidiasis. Ovarian hypoplasia exists in 55% of APECED cases in the third decade (289). Many different AIRE perturbations have been found in this autosomal dominant disorder, a pleiotropic condition (289) of varied expressivity. These include nonsense mutations and frameshifts, the latter confirming causation is not in doubt (289).

There is no evidence that any particular mutation leads to ovarian failure as distinct from other autoimmune phenomenon in the disorder's spectrum.

AIRE mutations have not yet been sought in women with POF who do not have non-ovarian features.

**88.2.9.20 Ovarian Leukodystrophy (Eukaryotic Translation Initiation Factor EIF2B).** Potentially, part of the same clinical constellation as cerebellar ataxia disorders having ovarian failure (see below) is a condition termed ovarian leukodystrophy. Characterized by MRI-detectable “vanishing white matter” leading to variable but progressive neurological degeneration, ovarian failure of varied expressivity coexists (290,291). As a result of mutation occurring in EIF2B, denatured stress-related proteins accumulate, of potential relevance to oogenesis given ubiquitous oocyte degeneration. In ovarian leukodystrophy, Fogli et al. (292) found variants in EIF2B2, EIF2B4 and EIF2B5. However, 0 of 93 cases with only isolated POF showed perturbations (293).

**88.2.9.21 Symphalangism and Noggin.** NOG is located on 17q22 and is responsible for the autosomal dominant disorder proximal symphalangism (SYM1).

Characteristic features include ankylosis of the proximal interphalangeal joints, carpal–tarsal fusion, brachydactyly and deafness. NOG is expressed in the ovary and is an antagonist of BMPs 4 and 7 (294). The latter are members of the TGF family of genes, some (e.g. BMP15) already considered as candidate genes for POF.

One SYM1 case has shown POF, and as predicted, an NOG mutation was found (295). NOG perturbations have not been sought in isolated POF subjects.

**88.2.9.22 Perrault Syndrome.** XX gonadal dysgenesis with neurosensory deafness is termed Perrault syndrome (296), an autosomal recessive disorder (297–299). Endocrinologic features seem identical to those of XX gonadal dysgenesis without deafness.

Candidate genes are likely to merge from the connexin family, for an attractive gene knockout model exists in connexin 37 (300). Null mice show gonadal failure due to arrest at the antral stage of oogenesis. The connexin gene family is responsible for many forms of congenital deafness in humans.

**88.2.9.23 Cerebellar Ataxia with XX Ovarian Dysgenesis.** Ataxia and hypergonadotrophic hypogonadism were first associated by Skre and colleagues (301), who described cases in two families. In one family, a 16-year-old girl was affected, whereas in the other family, three sisters were affected. In the sporadic case and in one of the three sisters, ataxia was observed shortly after birth; in the two other sisters, age of onset was later during childhood. Cataracts were present in all the cases reported by Skre et al. (301).

Hypergonadotrophic hypogonadism and ataxia were later reported by De Michele and colleagues (302), Gottschalk and colleagues (303), Fryns and coworkers (304), Nishi and colleagues (298), and Amor and coworkers (305). The nature of the ataxia differed among patients. Clinical findings similar to those of Skre and colleagues (301) were reported by De Michele and coworkers (302), Nishi and colleagues (298), and Amor and coworkers (305); ataxia was usually not progressive. Mitochondrial enzymopathy was found by De Michele and colleagues (306), but mitochondrial studies were apparently not performed by others. Cataracts were observed only by Skre and coworkers (301), and amelogenesis only by Linssen and colleagues (307). Neurosensory deafness reminiscent of Perrault syndrome was reported by Amor and colleagues (305) and Linssen (307), who wondered if this condition could be synonymous with Perrault syndrome. Mental retardation is also variable (305).

Overall, genetic heterogeneity must be assumed in the hypergonadotrophic hypogonadism disorders showing cerebellar ataxia. A single mutant gene is unlikely to explain every single case, but not every family need be unique.

**88.2.9.24 Forkhead Transcription 3A (FOXO3A).** Forkhead transcription genes other than FOXL2 cause ovarian follicular depletion in murine knockout models (135).

This holds true for FOXO3A, whose gene product regulates G1/S transition in granulosa cells. Of 60 POF cases (30 New Zealand; 30 Slovenia), 2 showed potentially significant FOXO3A mutations, neither present in controls (308). One mutation was a single heterozygous mutation in a Slovenian woman that resulted in a nonconservative amino acid charge (Ser421Leu); the mutation is potentially capable of inducing a conformational protein change. The other mutation was Arg506His, found in a New Zealand woman. This conservative change seems less likely to exert an untoward effect.

**88.2.9.25 FOXO1A.** Another forkhead transcription gene is FOXO1A. Watkins et al. (308) found a single conservative change (P84L) in FOXO1A among the 90 POF cases. The patient was Slovenian in ancestry.

**88.2.9.26 LIM DNA-Binding Proteins (LHX8).** LIM homeobox genes encode DNA-binding proteins. LIM family members contain two tandemly repeated domains that have cysteine-rich, double zinc finger motifs. LHX8 transcripts localize to mouse oocyte germ cells through antral follicles. Null mice lack germ cells (309). Qin et al. (310) sequenced all 8 LHX8 exons in 95 Caucasian women with POF. No novel single nucleotide polymorphisms (SNPs) were found.

**88.2.9.27 NANOS3.** NANOS3 is an RNA-binding protein. In mice, female and male knockouts are both infertile; female KO mice show no other phenotypic effect (311). Thus, human NANOS3 is a candidate gene for POF.

Human NANOS3 gene consists of two exons and is expressed in germ cells. In our study of 80 Chinese and 88 American Caucasians with POF, the only NANOS3 sequence variant found was a synonymous nucleotide substitution that was already known in the general population (312).

**88.2.9.28 GPR3 and GPs.** GPs are regulatory proteins. FHS, LH and other protein hormones are ligands for specific cell surface GPRs, leading to intracellular signal transduction. Widely disparate stimuli (e.g. hormones, light) also exert conformational changes on GPRs to allow binding to GPs. The oocyte-specific G-stimulating protein-coupled receptor GPR3 is known to have a role in maintaining meiotic arrest in the mouse oocyte. Female mice lacking GPR3 develop premature ovarian aging as a result of spontaneous resumption of meiosis in antral follicles, independent of the LH surge (313). Oocyte attrition results.

Located on chromosome 1, GPR3 consists of two exons. Our group interrogated GPR3 for perturbations in 82 Caucasian women with POF; none (0) of the 82 showed perturbations of significance (314). A single woman showed heteroduplex formation as a result of a heterozygous nucleotide substitution, C to A at position 51 (c.51C > A). However, this substitution does not alter the amino acid sequence, and had already been registered in the SNP database. GPR3 mutations have thus not yet

been shown to be a common explanation for POF in North American Caucasians.

**88.2.9.29 KIT.** KIT is an autosomal (4q12) gene that encodes for the tyrosine kinase transmembrane regulator for mast/stem cell growth factor (187). The c-kit receptor and its ligand (KL) constitute two murine loci known to be characterized by decreased germ cells: white spotting (W) and steel (L). Thus, human KIT is a good candidate gene for POF. Shibamura et al. (315) studied 40 women with unexplained POF, sequencing the entire coding region. One synonymous mutation was found but this is not a plausible disease-causing perturbation.

**88.2.9.30 RET Finger Protein-Like 4.** RING finger-like protein (RFLP) is expressed in oocytes and in mice exclusively in that organ. The gene encodes an E3 ubiquitin protein ligase which helps regulate protein degradation. Human RFLP4 is located on 19q13.4, and has been shown to interact with oocyte proteins of the ubiquitin-protease degradation pathway (316). In the context of a review in which details were not provided, Suzumori et al. (176) stated no mutations were found in Japanese POF patients with “46,XX POF.”

**88.2.9.31 MSH5 and DMC1.** Various pleiotropic syndromes that are associated with chromosomal abnormalities (e.g. ataxia telangiectasia and Bloom syndrome) have long been known to result in ovarian failure. Ataxia telangiectasia and Bloom syndrome (Table 88-4) are examples. Thus, genes perturbing meiosis are logical candidates for non-syndromic POF. The family of mismatch genes are pivotal in repairing DNA damage. Mutations lead to hereditary nonpolyposis colon cancer, as an example. Mandon-Pepin et al. (317) sought mutations in 44 POF women for SMC1, MSH4, MSH5 and SPO11. A heterozygous mutation (2547C > T) for MSH5 was found in one woman. Another woman showed homozygosity 3351 > AC in DMC1.

**88.2.9.32 AMH and AMHR Type II.** In addition to its role in Müllerian duct regression in males, MIS (AMH) is an oocyte inhibitor in the rat. Murine knockout models show early depletion of primordial follicles (318). Apparently, AMH plays a permissive or synergistic role in gonadal development as well. In humans, Wang et al. (289a) failed to find plausible perturbations in 16 POF cases.

**88.2.9.33 PTEN.** PTEN is a tumor suppressor gene, which as a regulator of cell growth could logically be related to POF. Shimizu et al. (319) failed to find perturbations in 20 women with idiopathic POF.

**88.2.9.34 Germ Cell Failure in Both Sexes.** See Section 88.2.5.13.

**88.2.9.35 46,XX Gonadal Regression (Agonadia).** Discussed above in the context of XY sex reversal (Section 88.2.5.13), agonadia in 46,XY individuals is characterized by absent gonads, abnormal external genitalia, and all but rudimentary Müllerian and Wolffian derivatives. Almost all affected individuals are 46,XY, for which reason a full description of the phenotype was

discussed previously in the context of 46,XY sex reversal. However, 46,XX gonadism is reported as well.

Mendonca and colleagues (320) reported gonadal regression without somatic anomalies in phenotypic sibs having unlike chromosomal complements (46,XY and 46,XX). Sporadic XX cases were reported by Duck and colleagues (145) and Levinson and coworkers (131). Kennerknecht and colleagues (321) reported gonadal regression, hypoplasia of the pulmonary artery and lung, and dextrocardia in XX and XY siblings.

Existence of these rare 46,XX case illustrates that the terms gonadism or gonadal regression are preferable to the appellation testicular regression.

**88.2.9.36 Malformation Syndromes with XX Gonadal Dysgenesis.** XX gonadal dysgenesis is found in several rare malformation syndromes. All are presumed autosomal recessive on the basis of multiple affected siblings: XX gonadal dysgenesis, microcephaly and arachnodactyly (322); XX gonadal dysgenesis and epibulbar dermoids (323); and XX gonadal dysgenesis, short stature, and metabolic acidosis (324). None have been elucidated fully.

**88.2.9.37 Other Nuclear Genes.** Over 200 murine genes cause male or female infertility (245) and often are expressed only in germ cells. Null (knockout) models in mice show germ cell deficiency or absence. The human homologs of these genes are attractive candidate genes for POF. Many remain to be interrogated for mutations in women with POF.

Attractive candidate genes include SOHLH1, SOHLH2, OBOX, NR6A1, TAF4B and BAX. These govern different mechanisms of gene action, some related to gonadotropins.

Continued interrogation of many genes is in order because it seems unlikely that any given gene will be responsible for more than perhaps 1–2% of POF. Whole genome associations using SNPs or CNVs are in progress and should identify chromosomal regions of interest. Novel genes can be anticipated. Nontraditional (non-Mendelian) mechanisms involving CNVs leading to nonhomologous allele recombination could also play a role.

**88.2.9.38 Mitochondrial Genes.** Perturbations of mitochondrial DNA cause a number of disorders, typically involving muscular and neurological systems. Perturbations of mitochondrial genes are good candidates for POF because the mature oocyte has the greatest number of mtDNA copies of any human cell. One gene is already proved so.

In progressive external ophthalmoplegia (PEO) proximal myopathy, sensory ataxia and parkinsonism occurs. This disorder results from a mutation in the mitochondrial gene polymerase gamma. Among seven families studied by Luoma et al. (325), POF co-segregated with PEO in three. The mutation Y955C was found in two of the three families. This tyrosine to cytosine change involves a highly conserved region, making a functional effect highly plausible. In the third family, compound

heterozygosity (N468D/A1105T) was observed in an affected woman. In another report, Pagnamenta et al. (326) studied individuals in three generations were affected with both PEO and POF. Y955C co-segregated with PEO.

## 88.2.10 Anomalies Limited to Internal Genital Ducts (Müllerian or Wolffian Derivatives)

**88.2.10.1 Imperforate Hymen.** The central portion of the hymen is ordinarily patent (perforate), permitting egress of mucus and blood. If the hymen is imperforate, mucus and blood from endometrial sloughing accumulate. Hydrocolpos or hydrometrocolpos results. The hymen is thin and distensible, unlike other types of vaginal obstructions with thick obstructions [e.g. transverse vaginal septum (TVS), vaginal agenesis or cervical atresia (CA)]. Vulvar distension thus may arise in imperforate hymen, uniquely suggesting the cause of hydrometrocolpos.

Affected siblings have been reported (327,328). Stelling and colleagues (329) reported concordant monozygotic twins; one twin had an affected daughter, who also had pyloric stenosis and possibly hip dislocation.

In the original description of Schinzel–Giedion syndrome, “hymenal atresia” was described (291a).

**88.2.10.2 TVS and McKusick–Kaufman Syndrome.** TVS are about 2 cm thick and usually located near the junction of the upper third and lower two-thirds of the vagina (1,330–332). Septa may, however, vary in location among different individuals (B in Figure 88-13). The uterus appears absent on vaginal exam, but can often be detected by rectal examination and should be evident by imaging (e.g. ultrasound or MRI). Gonads (ovaries) and external genitalia (female) are normal.

If existing in septa, perforations are typically central in location. If no perforation exists, mucus and menstrual fluid accumulate to produce hydrocolpos or hydrometrocolpos. Geneticists should appreciate that hydrometrocolpos is not a singular anatomic condition but rather merely a nonspecific physical feature that can arise as a result of having several different anatomic disturbances (e.g. imperforate hymen, TVS, vaginal atresia (VA), CA, and even incomplete Müllerian fusion (IMF)) (see Figure 88-14). Clinical presentation is similar in all except imperforate hymen. In imperforate hymen, a distended vulva and membrane are observed. In VA, TVS, and CA, the obstruction is thicker and no bulging is evident.

In the Amish, an autosomal recessive gene is responsible for TVS (333,334), and appears to be synonymous to that causing McKusick–Kaufman syndrome (MKS). The eponym was derived from recognition of an association between TVS with polydactyly and cardiac defects (333,335). Whether all cases of TVS—Amish and non-Amish—are caused by the MKS gene is uncertain but unlikely. Distinct genes could also exist in Amish

and non-Amish. Familial aggregates of MKS have been observed in the Italian and Puerto Rican populations (336), and in these families, VA seems relatively more common than TVS.

Making the hypothesis that only a single pleiotropic gene (MKS) exists, Chitayat and colleagues (336) analyzed 54 Amish individuals. Hydrometrocolpos was estimated to be present in 95%, polydactyly in 93%, and

**FIGURE 88-13** Photomicrograph of the left ovotestis of patient no. 2 of van Niekerk complement. Numerous primordial follicles are present in the smaller left portion; infantile testicular tissue is evident on the right. (From van Niekerk. *True Hermaphroditism—Clinical, Morphologic, & Cytogenetic Aspects*. Harper & Row: Hagerstown, 1974.)

cardiovascular malformations in 9%. In these cases, hydrometrocolpos was usually the result of TVS. Stone and coworkers (337) estimated penetrance to be 70% for hydrometrocolpos in women, 60% for polydactyly in either sex, and 15% for cardiovascular defects in either sex. Based on these estimates, 9% of men and 3% of women would have the MKS gene in a clinically nonpenetrant form.

The MKS gene product is a chaperonin, representative of that class of proteins that facilitates protein folding in conjunction with adenosine triphosphate hydrolysis (338). The MKS gene is localized on 20p12. Causation was deduced on the basis of H84Y/A242S compound heterozygotes co-segregating with the disorder in a large Amish pedigree (338). Each of these two chaperonin sequence differences (H84Y and A242S) is present in 1 per 100 Amish controls, a frequency (1%) in Amish consistent with a heterozygote frequency of that magnitude. Neither sequence was found in 100 non-Amish controls. Three Amish compound heterozygotes were unaffected, suggesting nonpenetrance higher than the 3–9% estimated on clinical grounds by Stone and coworkers (337).

Five other MKS probands showed no perturbations in the MKS chaperonin. In these cases, it was wondered if the diagnosis of Bardet–Biedl syndrome might not be more appropriate, given that Slavotinek and coworkers (339) showed that Bardet–Biedl syndrome can result

**FIGURE 88-14** Schematic diagram contrasting salient features of various anatomic defects capable of producing hydrometrocolpos or hydrocolpos. A bulging hymen would indicate imperforate hymen, but any of the following four conditions may appear similar. (A) VA. (B) TVS. (C) CA. (D) IMF with obstruction due to blindly ending hemiuterus. The distended hemiuterus can obliterate the vagina, making it difficult to identify the contralateral hemiuterus containing a cervix. TVS can exist at various sites. (Modified from Simpson, J. L. *Genetics of the Female Reproductive Ducts*. Am. J. Med. Genet. Semin. Med. Genet. 1999, 89, 224–239.)

from disturbance of the MKS gene. An atypical non-Amish patient of northern European descent with a frameshift mutation showed a hypoplastic clitoris with prominent labia majora, small ears, uterine and skeletal anomalies, and atrioventricular septal defects.

**88.2.10.3 Longitudinal Vaginal Septa.** Vaginal septa may be longitudinal as well as transverse (coronal or sagittal). Diagnosis of longitudinal vaginal septa (LVS) assumes absence of IMF (e.g. uterus didelphys), a condition in which the fusion defect extends inferiorly to produce a vaginal septum. In contrast to IMF (see below), isolated LVS need not necessarily be midline in position.

Usually, isolated LVS cause no clinical problems. If septa impede the second stage of labor, ligation and division may be necessary.

Heritable tendencies have not been reported in isolated LVS, but systematic studies have not been conducted. LVS has been observed in genetic syndromes, including Johanson–Blizzard syndrome (340) and the syndrome described by Edwards and Gale (341). The latter is an autosomal dominant syndrome characterized by LVS, hand anomalies and bladder neck anomaly.

**88.2.10.4 Vaginal Atresia.** In VA, the lower portion of the vagina, typically one fifth to one third of the total length, is replaced by 2–3 cm of fibrous tissue (see Figure 88-13). External genitalia are otherwise normal for women, except for absence of the hymen. Embryonic origin is presumed to involve failure of the urogenital sinus to contribute the caudal portion of the vagina. Superiorly, there lie a well-differentiated upper vagina, cervix, uterine corpus, and fallopian tubes. Diagnosis requires ultrasound, MRI, or rectal examination to verify presence of Müllerian derivatives, specifically the cervix and uterus. Women who lack not only most of the vagina but also the uterus do not have VA but rather Müllerian aplasia (MA) (see immediately below).

VA is clinically and embryologically distinct from TVS, even though in both conditions the upper vagina and uterus are intact. In TVS, an intact lower vagina exists, whereas in VA, it does not. In TVS, a thick intervening septum separates the lower from the upper vagina. In VA, fibrous tissue varies in amount and may sometimes replace nearly the entire vagina, beginning inferiorly near the perineum and extending superiorly to the cervix. Some confusion has arisen because in certain MKS cases, VA rather than TVS was observed (336). Although this could be taken as evidence that VA and TVS are the same condition, misclassification or genetic heterogeneity are equally plausible explanations.

No familial aggregates of isolated VA have been reported. However, VA is not uncommon in the context of multiple malformation syndromes (2,332). Of note is the syndrome described by Winter and colleagues (246). This autosomal recessive disorder is characterized by VA, renal hypoplasia or agenesis, and middle ear anomalies (e.g. malformed incus, fixation of the malleus and incus) (246,342). Other syndromes in which VA has been

reported include Antley–Bixler, Apert, Bardet–Biedl, Ellis–Van Creveld, Fraser (cryptophthalmos), Laurence–Moon, Pallister–Hall and Robinow syndromes (2,332).

**88.2.10.5 Müllerian Aplasia.** Aplasia of the Müllerian ducts leads to absence of the uterine corpus, uterine cervix, and upper (superior) vagina. This condition is the embryologic complement of VA, in the latter the lower vagina is absent but the upper vagina is present. In MA, the vagina is derived exclusively from urogenital sinus invagination. In MA, the ovaries are normal and, hence, secondary sexual development normal. Because most of the vaginal length is contributed by Müllerian derivatives, the vagina may be greatly shortened to only 1–2 cm. Vaginal length may or may not be adequate for coitus. By definition, there is no well-differentiated uterus, but bilateral remnants may and usually does persist in the form of cords. When gynecologists invoke the term “absence of the vagina” (in an otherwise normal woman) or “congenital absence of the uterus and vagina,” the diagnosis is usually MA (considered rigorously, the only other condition in the differential diagnosis is CAIS). The eponymic Rokitansky–Kuster–Hauser syndrome is considered synonymous with MA.

Affected sibships are well documented (343–345). Discordant monozygotic twins have also been recognized (346), indicating that a single autosomal recessive gene cannot explain all cases. Consanguinity does not appear to be increased. Carson and coworkers (347) studied 23 probandae and found no affected relatives. Similarly, van Lingen and colleagues (348) observed only one set of affected siblings among 35 cases. In the 1970s, sex-limited autosomal dominant inheritance was invoked by Shokeir (349) following the study of 16 Saskatchewan families. However, no subsequent studies have confirmed those findings.

Women with MA can still have genetic offspring, using ART. Because such women have normal ovaries, their oocytes can be stimulated and aspirated. Fertilization can then be achieved in vitro using the sperm from the husband or a donor, followed by transfer of the fertilized embryos into the (surrogate) uterus of a woman placed in hormonal synchrony with the probanda whose oocytes were aspirated. The surrogate woman then carries the pregnancy, but resulting offspring have the genetic constitution of the (MA) woman and her husband. Information on inheritance of this once genetically lethal disorder can thus be derived. Surveying United States ART programs, Petrozza and colleagues (350) identified 34 women with MA whose oocytes were used to produce a pregnancy carried in the uterus of a surrogate. Of the 17 resulting female offspring, none had MA; one male child had a middle ear defect and hearing loss. MA can thus be presumed to be polygenic/multifactorial in etiology. Using denaturing gradient gel electrophoresis, in the 1990s, various studies sought and found no molecular abnormalities in a number of candidate genes. However, these studies could probably completely exclude only

large deletions and studying WT1 (348) and PAX2 (351) no perturbations were found. This also held for AMH and AMHR (352). The N314 allele of GALT (352,353) was not increased. Perturbations of HOXA13 cause the autosomal dominant condition hand-foot-genital (HFG) syndrome (see later), but HOXA13 mutations have not been found in isolated MA. More recent and more detailed studies include those of Cheroki et al., who excluded 25 cases with WNT4, RAR-Gamma and RXR-alpha perturbations (354). Burel (355) found no perturbations in Hox genes (A7–A13) or PBX in a sample of six cases. Sultan et al. (356) studied 28 cases for mutations in WNT4, finding 1 heterozygous missense mutation (L12P).

All these studies involve very small sample sizes and all involve only European populations. Several groups have performed array CGH, (354,357–362) showing a variety of microdeletions and microduplications (i.e. less than the 5 Mb required for recognition by high-resolution CTG-banding studies). These include 1q21.1, 16p11.2, 17q12 and 22q11.2, all common variants. Familial transmission likely indicative of benign polymorphisms was not usually excluded, unfortunately because these regions are among those most commonly detected in array CGH studies irrespective of indication for performing (e.g. postnatal infant with developmental delay, fetus with ultrasound-detected anomalies). Del22q11.2 is probably most likely to play a role in certain cases, whether de novo or familial (if paternal). Microdeletions and microduplications of these regions are also found in normal individuals; thus, ascribing a causative role in MA is hazardous. An illustrative study receiving attention is that of Gervasini (363), who in a study of 30 MA cases found a duplication of Xq21 only in 5 MA cases (2 sporadic and 3 familial). Especially intriguing was a family of 2 affected MA sibs who received a 17-kb duplication from their father. Two sibs having a uterus failed to inherit the microduplication. The PAR duplicated contained SHOX, a homeobox gene that escapes X-inactivation and has been related to short stature if deficient and to Leri–Weill syndrome and Langer mesomelic dysplasia if duplicated (81,82). However, array CGH findings in MA were not confirmed in the much more robust study of Sandbacka et al. (364) of 101 cases. This study noted that all CNVs reported by Gervasini are in fact recorded in the Database of Genomic Variants and considered without phenotypic effect.

A molecular perturbation has been found in MA only in a very atypical case. Biason-Lauber et al. (365) found perturbations of WNT4 in many typical cases of MA in which virilization and adrenal insufficiency existed. The relevance to isolated MA is unclear. Gervasini et al. (363) found no perturbations in 12 MA cases who also had hyperandrogenism. Wnt4 acts before AMH and is required for initial Müllerian development (366), however, so plausibility could exist.

**88.2.10.6 MA and Malformation Syndromes.** MA may be one component of malformation syndromes, tabulated in Table 88-6 and discussed elsewhere by Simpson (2) and Simpson and Elias (2). The acronym MURCS has been applied when MA also coexists with renal and skeletal anomalies as well as facial clefts and cardiac anomalies (367). MA is not uncommon in the fascio-auricular-vertebral syndrome (Goldenhar syndrome) (368), limb/pelvis/uterus hypoplasia syndrome (369,370), and thalidomide embryopathy (371) and thrombocytopenia-absent radius syndrome (372). In the other disorders cited in Table 88-6, MA is uncommon.

**88.2.10.7 Incomplete Müllerian Fusion.** During embryogenesis, the paired Müllerian ducts fuse and canalize at the 150- to 200-mm stage, thereafter forming the upper vagina, uterus, and fallopian tubes. When the two ducts fail to fuse and canalize, IMF exists. Specific terms are applied to various subtypes that exist, as discussed elsewhere (1,332). Failure of fusion of Müllerian ducts may result in two hemiuteri, for example, each associated with no more than one fallopian tube. If one Müllerian duct fails to contribute to the definitive uterus, a rudimentary horn results. If one uterine horn is atretic, ipsilateral renal agenesis is especially common.

Many familial aggregates of IMF have been reported, including multiple affected siblings, as well as affected mother and daughter (373,373a,374–381). In the same kindred, affected relatives may show different forms of IMF (373a). The single formal genetic study involved only 24 index cases (373), finding 1 of 37 (2.7%) sisters to have a clinically symptomatic uterine anomaly. Such a recurrence risk for first-degree relatives is consistent with predictions based on polygenic/multifactorial etiology (2–3%). No molecular studies have been conducted in isolated IMF, but below we will note that perturbation of HOXA13 causes HFG syndrome. Several other candidate genes are worth exploring, such as Wnt7a, which is required in mice for completion of Müllerian differentiation (382).

**88.2.10.8 IMF and Malformation Syndromes.** More than a dozen malformation syndromes have IMF as one component (2,382). In Fryns syndrome, Halal syndrome, and hydrolethrus syndrome, IMF is consistently observed. IMF is less commonly observed in the other disorders listed in Table 88-7.

**88.2.10.9 HFG Syndrome.** HFG syndrome is an autosomal dominant disorder characterized by IMF, skeletal anomalies, and urologic anomalies. Skeletal anomalies include short first metacarpals, small distal phalanges on the thumbs, short middle fifth phalanges, and fusion of various wrist bones (306,380). The great toe is short because of its shortened metatarsal; the distal phalanx is small and pointed. Urinary system abnormalities include urinary incontinence in women, a ventrally displaced urethral meatus (men and women), and malposition of the ureteral orifices

**TABLE 88-6 Malformation Syndromes with Müllerian Aplasia<sup>a</sup>**

Syndrome	OMIM Number	Somatic Anomalies	Etiology
Fraser	219000	Cryptophthalmia, nose and external ear anomalies, stenotic larynx, skeletal defects, syndactyly, renal agenesis, large clitoris, and labia majora, mental retardation	Autosomal recessive
Meckel–Gruber	249000	Microcephaly, posterior encephalocele, eye anomalies, cleft palate, polydactyly, polycystic kidneys	Autosomal recessive
MURCS association	601076	Renal aplasia, cervicothoracic somite dysplasia, Klippel–Feil anomaly, deafness, short stature	Unknown; probably heterogeneous
Thalidomide teratogenicity		Nasal hemangioma, neurosensory hearing loss, ear anomalies, limb reduction defects, visceral anomalies	Teratogen
Urogenital adysplasia, hereditary (hereditary renal adysplasia; bilateral renal agenesis)		Oligohydramnios, flattened (Potter) facies, pulmonary hypoplasia, unilateral or bilateral absent kidneys, limb deformities	Autosomal dominant
Winter	247990	Lacrimal duct stenosis, external and middle ear anomalies, renal agenesis	Autosomal recessive
Kumar		Skeletal anomalies	Unknown

<sup>a</sup>Several of these syndromes could be heterogenous, that is, more than one entity. In particular, Klippel–Feil and Müllerian aplasia above could be a distinct entity, as could deafness and Müllerian aplasia.

From Simpson, J. L. Genetics of the Female Reproductive Ducts. *Am. J. Med. Genet.* 1999, 89, 224–239.

in the bladder wall of women (380). These urologic anomalies are distinct from those associated with isolated IMF, which more often is associated with the absence of one kidney, pelvic kidney, or duplication or absence of ureters. Vertebral anomalies in IMF also differ in type from those in HFG.

First reported by Stern and colleagues (383), many familial aggregates of HFG have been reported (306,380,384–387). The disorder is caused by perturbation of HOXA13, localized to 7p14–p15. Studying a member of the original HFG family reported by Stern and colleagues (383), Mortlock and Innis (388) found an HOXA13 nonsense mutation that resulted in a highly conserved tryptophan being converted to a stop codon, truncating the protein by 20 amino acids. In one of three HFG individuals studied by Goodman and coworkers (386), an HOXA13 mutation again involved a stop codon. In a second family, an expansion of the polyadenosine (poly A) tail was noted, suggesting a dominant-negative mechanism.

Goodman and colleagues (386) later studied six additional families, two previously not studied and four previously reported. In three families, nonsense mutations resulted in a truncated protein. In another family, originally described by Hennekam (389), the N-terminal polyalanine tract was again expanded, suggesting a dominant-negative effect. In a fifth family, a missense mutation was present, altering an invariant asparagine residue in the homeodomain recognition helix that is necessary to target DNA. In a final family, no HOXA13 mutation was found. In 2002, Utsch and colleagues (390) reported poly A expansion in a five-generation HFG family, giving further support to a dominant-negative mechanism in some cases.

In conclusion, perturbation of HOXA13 clearly causes HFG. Pathogenesis could be interpreted as resulting from a null allele (haploinsufficiency) if we are to assume that the polyalanine expansion mitigates against action of HOXA13. HOXA13 is clearly integral for both skeletal development and Müllerian fusion.

**88.2.10.10 Persistent Müllerian Derivatives in Males.** The uterus and fallopian tubes (Müllerian derivatives) may persist in ostensibly normal (46,XY) males. External genitalia, Wolffian (mesonephric) derivatives, and testes develop as expected for males, and pubertal virilization occurs.

Testes are presumed to differentiate normally, but they may not remain normal. One or more testes may be present in the intra-abdominal or inguinal region, and they undergo secondary degeneration. About 5% of individuals develop a seminoma or other germ cell tumor. Testes in persistent Müllerian derivatives (PMDs) are also abnormally mobile (3) as a result of not being anchored properly to the processus vaginalis. Increased mobility could predispose to testicular torsion and secondary testicular degeneration, which are frequent in PMD (63). Infertility is common for these and perhaps other reasons.

Two genes are integral for precluding Müllerian development in men. One gene codes for AMH (formerly called MIS); the other gene codes for the AMHR. Josso and colleagues have studied AMH and AMHR in over 100 PMD families; in 15%, no mutation was identified (391). Mutations are equally likely to involve AMH or the AMHR. In a 2005 report, 82 cases of PMD in men were analyzed by Josso and coworkers (392). Of these,

**TABLE 88-7 Selected Multiple Malformation Syndromes in Which Incomplete Müllerian Fusion**

Syndrome	OMIM Number	Somatic Anomalies	Etiology
Bardet–Biedl	209900	Retinal pigmentary degeneration (retinitis pigmentosa), polydactyly, obesity, mental deficiency	Autosomal recessive
Beckwith–Wiedemann	130650	Macroglossia, omphalocele, macrosomia	Autosomal dominant, after uniparental disomy
Donohue (leprechaunism)	24200	Elfin facies with thick lips; large, low-set ears; prominent breasts and external genitalia; hirsutism; abnormal carbohydrate metabolism; failure to thrive; motor and mental retardation	Autosomal recessive
Fraser	219000	Cryptophthalmia, external ear and nose anomalies, laryngeal stenosis, syndactyly, skeletal defects, renal agenesis, large clitoris and labia majora, mental retardation	Autosomal recessive
HFG	140000	Metacarpal and metatarsal anomalies, malformed thumbs, displaced urethral meatus, urinary incontinence	Autosomal dominant
Johanson–Blizzard	243800	Deafness, hypoplastic alae nasi, primary hypothyroidism, mental retardation	Autosomal recessive
Laryngeal atresia	607132	Hydrocephaly, complete or partial laryngeal obstruction, tracheoesophageal fistula or atresia, renal hypoplasia, varus deformity of feet	Unknown
Meckel–Gruber	24900, 603194 607301	Microcephaly, posterior encephalocele, eye anomalies, cleft palate, polycystic kidneys, polydactyly	Autosomal recessive
Roberts	268300	Sparse, silvery blond hair; midfacial hemangioma; cleft lip with or without cleft palate; limb reduction defect; intrauterine growth retardation	Autosomal recessive
Cavalcanti		Tibial aplasia, triphalangeal thumb, micratia, scaliosis, club foot (Müllerian aplasia also reported)	Unknown
Rudiger	268650	Bifid uvula, coarse facies, absent ear cartilage, hydronephrosis secondary to ureterovesical stenosis, short digits	Autosomal recessive
Thalidomide teratogenicity		Nasal hemangioma, neurosensory hearing loss, ear anomalies, limb reduction defects, visceral anomalies	Teratogen
Trisomy 18		Prominent occiput, malformed ears, micrognathia, short sternum, cardiac defects, horseshoe kidney, overlapping fingers, intrauterine growth retardation, severe development retardation	Chromosomal aneuploidy
Trisomy 13		Microcephaly, microphthalmia, malformed ears, cleft lip and palate, cardiac anomalies, polydactyly, intrauterine growth retardation, severe developmental retardation	Chromosomal aneuploidy
Urogenital dysplasia, hereditary (hereditary renal agenesis)		Oligohydramnios, flattened (Potter) facies, pulmonary hypoplasia, unilateral or bilateral absent kidneys, limb deformities	Autosomal dominant

From Simpson, J. L. Genetics of the Female Reproductive Ducts. *Am. J. Med. Genet.* 1999, 89, 224–239.

38 showed an AMH mutation, 33 an AMHR mutation, and 11 neither (392).

**88.2.10.10.1 AMH Mutation.** Located on 19p13.3, AMH consists of five exons (Figure 88-15). The 3' end is guanine cytosine rich. The AMH gene product can be measured by enzyme-linked immunosorbent assay, but results are informative only before sexual maturation. AMH production is suppressed after puberty. When AMH is not detected, a mutation in the structural gene can usually be demonstrated. Although Imbeaud and coworkers (393) initially failed to detect recurrent AMH mutations in 19 PMD families (molecular heterogeneity),

recurrent mutations were later found (394). In a 2005 tabulation, 38 different mutations were found in 46% of families studied (392). Most mutations were homozygous and found in individuals of North African (Arab) or Mediterranean descent.

**88.2.10.10.2 AMH Receptor.** The AMHR II gene is located on 12q13.12. It consists of 11 exons (Figure 88-15) and is 8700 bp in length. AMHR II mutations have now been found throughout the gene. Compared with AMH-negative cases, AMH-positive cases are relatively less likely to be found in north African Arab populations.

**FIGURE 88-15** Diagram of MKS structure and mutations. Exons are shown as rectangles with alternate splicing of exons 1a and 1b as indicated. The sequence alterations of the Old Order Amish chromosome are H84Y and A242S. (Data from Stone, D. L.; Slavotinek, A.; Bouffard, G. G., et al. *Mutation of a Gene Encoding a Putative Chaperonin Causes McKusick-Kaufman Syndrome*. *Nat. Genet.* 2000, 25, 79–82.)

If AMH is elevated, an AMHR mutation should be suspected. Most mutations found are missense, generally occurring throughout the gene. Mutations in exon 1 and in the 3' portion of exon 5 are most common. The most frequent single perturbation is deletion of 27 bp in exon 10 (del 6331–6357). When present, the deletion exists in homozygous form in 42% of case; compound heterozygosity exists in 58%, the deletion coupled with a missense mutation (394). For diagnosis, Belville and coworkers (394) recommend polymerase chain reaction to detect the 27-bp mutation, followed by sequencing the entire AMHR gene if the deletion is not present in homozygous form.

Women (46,XX) with AMHR mutations undergo puberty normally (394). Actually, this is a mild surprise because transgenic XX mice that chronically express AMH show gonadal abnormalities (5). Granulosa cells also normally produce AMH (395,396), for which reason a role for AMH in gonadal development seems plausible.

**88.2.10.11 CAVD and CF.** Almost all men with CF are infertile, specifically as a result of CAVD (CBAVD). At least 70% if not almost all men with CBAVD have one or more mutations in CFTR. The most common CF mutations causing CAVD are  $\Delta F508$  and W128X.

In addition to the missense and nonsense mutations in CFTR causing classic CF with pancreatic and pulmonary pathologies, a deleterious polymorphism of specific relevance to CBAVD exists when 5-thymidines (5-T) are present in a particular location in intron 8 (397). The 5-T polymorphism (allele) results in very low (10%) transcription of CFTR from that chromosome (cis), owing to improper exon–intron splicing and subsequent loss of exon 9. The 7-T polymorphism has less effect, and 9-T none. If 5-T “polymorphism” is homozygous, CBAVD results. Classic CF (pulmonary and pancreatic diseases) does not result because the 10% CFTR gene product is sufficient for normal lung and pancreas function.  $\Delta F508/5-T$  compound heterozygosity leads to CBAVD. However, if 5-T exists cis with R117H, that chromosome produces no CFTR. Thus,  $\Delta F508/R117H + 5-T$  results in classical CF with pancreatic and pulmonary symptoms.

For purposes of genetic counseling, CAVD cases should be assumed to involve compound heterozygosity for two mutant CF alleles or one CF allele and the 5-T variant. It

should be assumed that both CF alleles are dysfunctional, even if one or both are not diagnostically evident. The exception arises if unilateral renal aplasia is present (398).

## 88.2.11 Miscellaneous Disorders

**88.2.11.1 Absence of Testes (Anorchia).** Males (46,XY) with unilateral or bilateral anorchia have unambiguous male external genitalia, normal Wolffian derivatives, no Müllerian derivatives and no detectable testes (1,111). Testicular tissue is not detected in the scrotum, the inguinal canal, or the entire path along which the testes descend during embryogenesis. Splenic–gonadal fusion can mimic the disorder. Unilateral anorchia is asymptomatic and not extraordinarily rare. Bilateral anorchia is far less common. Somatic abnormalities do not ordinarily coexist.

Despite the absence of testes (anorchia), the phallus is well differentiated. Pathogenesis presumably involves atrophy of fetal testes after 12–16 weeks' gestation, by which time male genital differentiation has occurred. Vasa deferentia terminate blindly, often in association with spermatic vessels.

Heritable tendencies exist (399), but recognition of monozygotic twins discordant for bilateral anorchia (400) has long indicated that genetic factors are not paramount. Pathogenesis could involve in utero torsion of the testicular artery, which is known to have a heritable tendency (401,402).

Anorchia is a component of several malformation syndromes in which the external genitalia are unequivocally male. These include Cross syndrome (403), the OEIS syndrome (omphalocele, extrophy, imperforate anus, and spine deformity) (177,404), Saldino syndrome (405) (cone-shaped epiphyses), and sirenomelia. (Anorchia as the sole anomaly has also been observed in an unusual family in which an SF1 mutation was segregating.) Family members with this mutation showed a wide variety of phenotypes, ranging from XY sex reversal to hypospadias to anorchia. Philibert et al. (148) sought SF1 mutations in various conditions and found R114Q in a boy whose only abnormality was anorchia.

**88.2.11.2 Absence of Ovary and Fallopian Tubes.** Otherwise normal females may show absence of one ovary, usually in conjunction with ipsilateral absence of the fallopian tube (406,407). Pathogenesis probably involves congenital absence of a vessel or the occurrence of a vascular accident (torsion). These hypotheses are analogous to those invoked for anorchia.

**88.2.11.3 Accessory or Malpositioned Gonads.** Two ovaries or more than two testes may exist in a single individual (408,409).

Polyorchidism is far more common than polyovaries, with more than 100 cases of polyorchidism being reported (408,410). In half of patients, the testes are scrotal; in other cases, maldescent may exist, sometimes with intra-abdominal gonadal location. Gonads may also be located near the kidneys (411) or fused to the spleen (412). No familial aggregates have been reported.

## Cancer of the Breast and Female Reproductive Tract

*Ora Karp Gordon*

GenRisk Adult Genetics Program, Cedars-Sinai Medical Center, Los Angeles, CA, USA

This article is a revision of the previous edition article by C Michael Steel, volume 2, pp 2093–2121, © 2007, Elsevier Ltd.

### 89.1 HISTORICAL BACKGROUND: MAPPING BREAST CANCER GENES

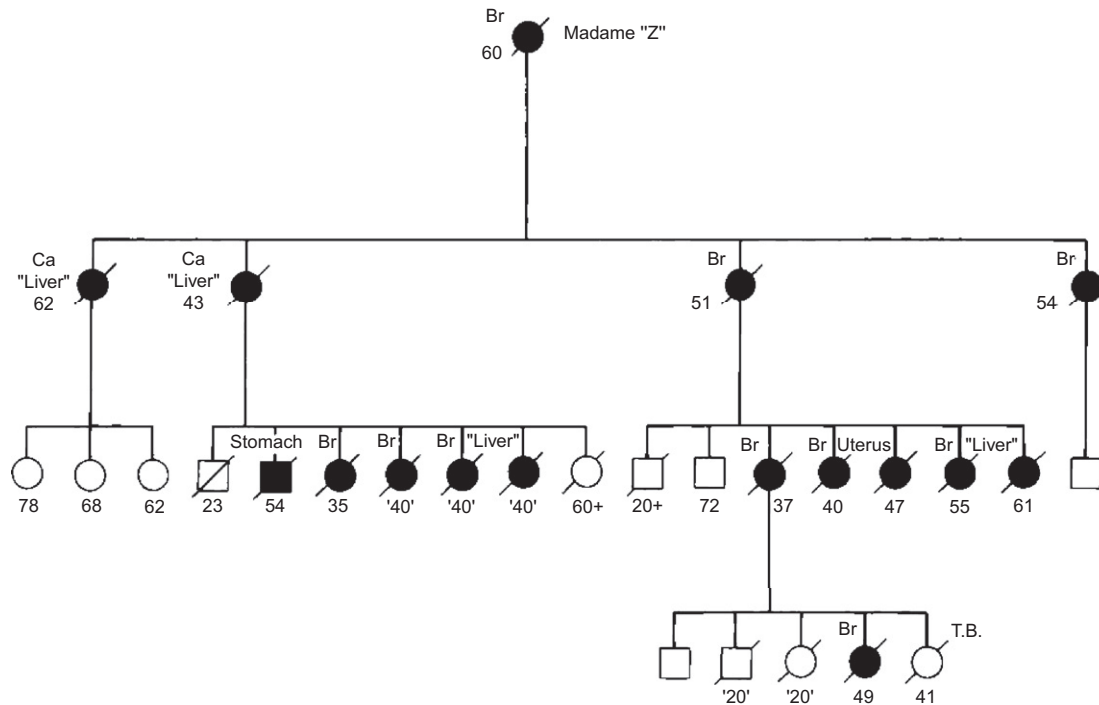

It has long been clear that the resolution of many controversies—the overall scale of the genetic contribution to breast cancer, the number of major genes implicated and their modes of inheritance, the distinctions between different clinical types of breast cancer family, and the relationship between genetic and environmental factors in breast cancer etiology—could come only through identification and characterization of the relevant genes. Despite many serious attempts at linkage analysis and a number of tentative claims (1), no real progress was made until 1990. That year, the association between germline mutations in p53 and at least some instances of Li-Fraumeni cancer family syndrome was reported (2,3). Some months later, a LOD score of +5.98 was found for the CMM86 locus on chromosome 17 at q21 in a subset of breast cancer families characterized by mean age of onset before 45 years (4). The latter association had been found through a systematic screen of mapped polymorphic markers, because unlike polyposis coli or retinoblastoma, no helpful cytogenetic clues to the location of genes implicated in human breast cancer were forthcoming.

### 89.2 DISCOVERY OF BRCA1

Support for a candidate gene locus on 17q came promptly (5) when three of five large breast/ovarian cancer families were shown to give substantial positive LOD scores with CMM86; thereafter, an international consortium effort was launched, using six 17q markers to improve the accuracy of mapping the breast cancer locus and to establish the characteristics of 17q-linked cancer families. These families all came from pedigrees that were reminiscent of “Madame Z,” the original hereditary breast-ovary family described by Dr Broca in 1898 (Figure 89-1). In April 1993, results were reported for 214 families by Easton and colleagues (6) who indicated that the gene

termed “BRCA1” lay approximately 20 cm centromeric of CMM86 and that the great majority of families with breast/ovarian cancer—but only some 45% of families with breast cancer without ovarian cases—were linked to it. There was much stronger evidence for linkage in families with mean age of onset younger than 45 years and evidence against linkage in families that included one or more male breast cancers. These findings gave enormous impetus to subsequent attempts to clone BRCA1. They also provided important insights into the genetic heterogeneity of familial breast cancer: first, by distinguishing male breast cancer families from the rest, and second, by suggesting that within the BRCA1-linked set are subsets characterized by very different relative risks (RRs) of breast and ovarian cancers (7). Nevertheless, Easton and colleagues highlighted some of the inherent difficulties of classic genetic studies in this situation. Only large multi-case families can provide much linkage information, and these may be atypical, particularly with respect to penetrance of the trait. Unaffected family members are usually treated as uninformative, which may also distort estimates of penetrance. Furthermore, even a single sporadic case of cancer in a large family may cast doubt as to linkage, and because sporadic cases are likely to occur more frequently in older subjects, this may contribute to the disparity in LOD scores for families with different mean age of onset.

The cloning of BRCA1 was accomplished through a long and labor-intensive search of yeast artificial chromosomes and cosmids from the appropriate region. Ultimately, Skolnick’s group and their collaborators at the University of Utah and Myriad Genetics identified mutations that cosegregated with the disease in affected members of five of eight breast cancer kindreds, only four of which had substantial positive LOD scores for 17q12 markers, although the others showed haplotype sharing at this locus for at least three affected members (8). The gene implicated (Figure 89-2) is a large one, with

**FIGURE 89-1** Illustration of the family tree Madame "Z". The original hereditary breast ovary family described by Dr Paul Broca in France in 1852. Most commentators believe it was his wife's family.

#### BRCA1

#### BRCA2

**FIGURE 89-2** Exon/intron maps of the human BRCA1 and BRCA2 genes. Exon 1 is not transcribed in either genes. Some of the mutations identified in early studies are indicated below the gene map. Note that already two recurring mutations (deletion of AG in exon 2 and insertion of C in exon 20) were recognizable. (From Simard, J.; Tonin, P.; Durocher, F., et al. *Common Origins of BRCA1 Mutations in Canadian Breast and Ovarian Cancer Families*. Nat. Genet. 1994, 8, 393–399.)

24 exons spanning some 100kb of genomic DNA and encoding a protein of 1863 amino acids.

The initial stages of the search for BRCA2 have been described earlier. Once linkage to the proximal region of 13q had been established, this again became a mapping race. The gene was identified, and a partial sequence, including documentation of some mutations, was published by Stratton's group from the Institute of Cancer Research, London (9). A more complete sequence and further mutations were reported by the Myriad Genetics team a few months later (10).

On the basis that most families with breast and ovarian cancers are linked to BRCA1, Easton and colleagues (6) used the excess of observed over expected breast cancers in relatives of ovarian cancer patients (and vice versa) to

calculate the population frequency of relevant BRCA1 mutations. If all the excess is attributable to high-penetrance BRCA1 mutations, the overall frequency of these is in the order of 0.0007 (i.e. about one in 700 women worldwide is a heterozygous carrier). A similar result was derived by Peto and colleagues (11) from the frequency of identified mutations in breast cancer patients, the estimated penetrance, and the efficiency of mutation detection. It may appear to be very low compared with the figures quoted earlier, which were derived from segregation analyses, but there is an important distinction between mutations at any one locus and the cumulative frequencies of all mutations at any loci that may predispose to breast or ovarian cancer. Furthermore, in most calculations of gene frequency from epidemiologic data,

there is an inverse relationship between penetrance and frequency. Thus, if some BRCA1 mutations carry lifetime risks for cancer substantially lower than 80%, their frequencies may be considerably higher than the above-mentioned figure suggests (12).

In addition to breast and ovarian cancers, early studies indicated that BRCA1 mutations confer lifetime risks for colon and prostate cancers that are some three to five times higher than the population average (13). Subsequently, these findings have been only partially confirmed: the pancreatic cancer risk is significantly elevated in BRCA2 as is the prostate cancer risk, but other cancers, including pancreatic, cervical, and uterine cancers, have been reported as overrepresented among mutation carriers. However, the numbers of family members included in the initial surveys only permitted reliable calculations to be made in respect to common tumors (14–16). In the past few years, the colon cancer risk has been largely dismissed (17), and there has been a significant controversy over the potential contribution to endometrial cancer, specifically the papillary serous endometrial cancer (18). Most of them now agree that endometrial cancer is not an independent cancer risk in BRCA carriers and that the excess endometrial cancer is due to the use of tamoxifen (19).

### 89.3 DISCOVERY OF BRCA2

A collection of 22 breast cancer families with at least one affected male relative was assembled, also through the auspices of the international consortium. Formal exclusion of linkage to BRCA1 was reported by Stratton and colleagues (20) (aggregate LOD of  $-16.63$ ). A few months later, results were published (9) about a systematic linkage screen on 15 large breast cancer kindreds not linked to BRCA1 (including six with affected male relatives) that localized a second breast cancer susceptibility locus (BRCA2) to human chromosome 13 at q12–13, proximal to the retinoblastoma gene. All but one of the families with affected male relatives gave some evidence of linkage (multipoint LODs  $+0.15$  to  $+3.70$ ) but so also did four of the five families with breast and ovarian cancer patients (multipoint LODs  $+0.86$  to  $+3.70$ ). Five of the families included both affected male relatives and patients with ovarian cancer. The conclusion was that BRCA2 is implicated in a substantial proportion of those families with breast cancer not linked to BRCA1. The conclusion also indicated that involvement of BRCA2 carries a high risk for female breast cancer—penetrance figures of up to 87% by age 80 have been presented, although this is probably a high estimate (13,21–23) and appreciable, though lower, risks for male breast and ovarian cancers. Other cancers overrepresented in families with BRCA2 include prostate, pancreatic, and ocular melanoma (24,25). The gene was cloned in December 1995 (9,10) and shows only minimal homology with BRCA1.

#### 89.3.1 Identification and Characterization of BRCA1 and BRCA2

BRCA2 is even larger than BRCA1, with 27 exons encoding a protein of 3418 amino acids. Both are transcribed in several tissues, most abundantly in developing thymus and testis and also in the breast and ovary. There is only minimal homology between them and little homology to any other known genes, apart from a ring finger domain at the N-terminus of BRCA1 and a heptad repeat element in the middle of the protein, which might enhance dimerization. Both are common characteristics of DNA-binding proteins such as transcription factors. Neither feature is found in BRCA2. Both BRCA1 and BRCA2 are involved in multiple functions, including homologous recombination (HR), DNA repair, and transcriptional regulation (26–28). There is also evidence that BRCA1 is an important link in the signal chain that starts with recognition of DNA damage (sensed by ATM) and leads to cell cycle arrest at the G2/M checkpoint (29,30). BRCA1 is a 220-kD nuclear phosphoprotein. DNA checkpoint-associated kinases such as CHK2, ATM and RAD51 phosphorylate various specific residues of BRCA1 when the cell has undergone DNA damage, making the cells more or less sensitive to environmental stressors (31).

As in the case of BRCA1, there are truncating mutations throughout the BRCA2 gene, and these include small deletions, insertions, and nonsense base substitutions in coding regions, splice sites, and regulatory elements. In BRCA1, large genomic deletions covering several exons account for a substantial proportion of germline mutations, particularly in the Dutch population (32). As in the case of BRCA1, certain recurring founder BRCA2 mutations have been identified in particular populations. These include 6174delT in Ashkenazi Jews and 999del5 in Icelanders (33,34).

Data on BRCA1 and BRCA2 mutations are listed on a National Human Genome Research Institute Web site, the Breast Cancer Information Core, but information on mutations and particularly variants of uncertain clinical significance is not consistently and uniformly added to the database. Initially, in several genetically homogeneous populations, recurrent mutations were identified in BRCA1, BRCA2, or both (Figure 89-2). These include the Ashkenazi Jewish mutations, the Icelandic BRCA2 999del5, and the major BRCA1 gene deletions in Dutch families already mentioned, which make up the majority of mutations detected within those populations. There are also at least four recurring BRCA1 mutations in Norwegian families (35,36) and at least two (BRCA1 2800delAA and BRCA2 6503 delTT) characteristics of Scottish/Irish families, including many now living in North America (37), but now there have been recurrent mutations detected worldwide. Though not of the same frequency, recurrent “founder” mutations are seen in numerous population isolates, including as divergent populations as west Africa, Japan, Pakistan, and Italy (Table 89-1).

**TABLE 89-1** Significant BRCA1/2 Founder Mutations in Populations Worldwide

Frequency of founder mutations and proportion of breast and ovarian cancers related to BRCA mutations vary widely. Ethnic and geographic isolation increases likelihood of founder mutations.

Reprinted with permission from: Ferla, R., et al. Founder Mutations in BRCA1 and BRCA2 Genes. *Ann. Oncol.*, 2007, 18, Suppl 6, vi93–vi98.

Interestingly, when appropriate studies have been undertaken, it appears that common mutations in different families usually entail preservation of a shared haplotype, as defined by a number of polymorphic intragenic and close-flanking markers, even when the families concerned appear to be from widely separated geographic regions and communities (38). This not only suggests founder effects rather than mutational “hot spots” as the basis for the recurrent mutations but also points to a high degree of genetic stability at this locus, over many centuries, with a remarkably low rate of new mutations.

There have been only a few case reports published in the world on confirmed de novo mutations but have been recorded in both *BRCA1* and *BRCA2* (39).

In the general population, it is estimated that about 1 in 500 people (of either gender) carry a *BRCA1/2* mutation (40) (Table 89-3). Due to population genetic effects, geographically or socially isolated populations or mass genocide resulting in a narrow reproductive pool, certain recurrent mutations are fairly frequent in some populations (Table 89-1) (41,42). Example populations include eastern European Ashkenazi Jewish, French Canadian and Icelandic populations where the prevalence of *BRCA* mutations can be as high as 1 in 45 (34). Common recurrent mutations also have been described in Polish and Filipino populations (43). Afro-American and Afro-Caribbean populations have not been as extensively studied, but the *BRCA1* 943ins10 mutation is a very old west African founder mutation (44) and has been tracked through the West Indies and the United States (45). *BRCA* carrier frequency is 32% among breast/ovary cancer families in Japan, equal to Ashkenazi Jewish women, although Pakistan has the highest rates of breast and ovarian cancers in Asia, also due to recurrent founder *BRCA* mutations (41,46). The frequency of mutations found among Israeli Ashkenazi Jewish women with ovarian cancer, even without any family history, is more than 30% (47).

## 89.4 PATHOLOGY OF FAMILIAL BREAST CANCERS

One of the early noted features of familial breast cancers is that they tend to show an excess of the unusual medullary histologic type, although allowance must be made for the early age of onset that characterizes both familial breast cancers and those with medullary features on histology (36,48,49). One comprehensive survey (50) has found that when adjusted for age of onset, breast cancers arising in members of families with strong evidence of genetic predisposition are not overall strikingly different from those that occur in the population at large. Most are invasive ductal tumors of “no special type,” according to the World Health Organization breast cancer classification. However, there are significant differences within the general category of familial cancers. Initial histologic observations in tumors in probable *BRCA1* mutation carriers (defined by genetic linkage) were predominantly aneuploid, with a DNA index in the hyperdiploid range and with a high S-phase fraction, indicating rapid proliferation. In contrast, tumors from non-*BRCA1*-linked families showed a significant excess of cases with tubular or lobular features on histology, suggesting that there may be a separate genetic basis for a subset of breast cancers belonging to these (related) pathologic types. A review of the pathology of breast tumors from *BRCA1* and *BRCA2* mutation carriers has been conducted under the auspices of the Breast Cancer Linkage Consortium. The above-mentioned findings were essentially confirmed

and extended. Cancers associated with germline BRCA1 mutations tend to have the appearances of high grade (e.g. extreme pleomorphism, high mitotic index and S-phase fraction, and little tubule formation). The majority are estrogen receptor (ER)-negative, but in contrast to most high-grade sporadic tumors, they also tend to show low expression of Erb-B2 (Her-2, neu). This is referred to as the “basal phenotype.” BRCA2 tumors show similar features, but the majority (80%) are hormone-positive (51). Likewise, BRCA1 tumors (but not those with BRCA2 mutations) tend to show substantial lymphocytic infiltration. Both categories were noted to show continuous “pushing” margins, apparently compressing rather than invading adjacent tissues (21,52,53). On the basis of histologic appearances, an experienced pathologist may suggest an underlying BRCA mutation even in the absence of a known family history. Cytokeratin 5 and 14 have been shown to have high predictive value for underlying germline BRCA1 mutation (54). It has been suggested that since BRCA1 tumors are so often ER-negative, a cell of origin effect is reflected and it is intrinsic. Since the 20% of ER-positive tumors seen in BRCA1 carriers tend to occur in older women, these cancers may be incidental or “phenocopies” and not a consequence of the BRCA1 deficiency (55,56). Tung and colleagues have shown that loss of heterozygosity for BRCA1 is associated with about half of ER-negative sporadic breast cancers but 97% of BRCA1 carriers, regardless of whether the cancer was ER-positive or ER-negative, and that there was significant skewing toward loss of the wild-type (wt) allele, suggesting that the mutant allele has a role in the ER-positive tumors as well (57).

As in the Marcus study (50), familial breast cancers not attributable to BRCA1/2 mutations tend to have distinctly favorable prognostic features, being generally of low histologic grade and including well-differentiated tubular and lobular categories (53). In keeping with the epidemiologic and histologic evidence for fundamental differences among the various categories of familial breast cancer, molecular analysis at the level of both DNA structure and gene expression shows that tumors associated with germline mutations in BRCA1 or BRCA2 are distinct from each other and from non-BRCA tumors (58,59).

### 89.5 BRCA1 AND BRCA2 MUTATION ANALYSIS

Because BRCA1 and BRCA2 are so large, searching for mutations is a major undertaking. The procedure involves amplification of the exons and the intronic splice junction sites with suitably chosen polymerase chain reaction (PCR) primer pairs. The original BRCA1 study (8) used 25 such pairs, but more than 50 have now been documented (60), including 24 for exon 11, which comprises approximately 60% of the coding sequence. For BRCA2, the number of primer sets required is even greater. Ideally, the PCR products should be no more than 300 bases

long. They may be sequenced directly or tested for the presence of a mutation by an indirect approach such as the single-strand conformational polymorphism (SSCP) assay, denaturing gradient gel electrophoresis, and heteroduplex analysis or mismatch cleavage (chemically enhanced or by bacterial resolvase). None of these indirect methods can guarantee detection of all mutations (61,62). SSCP was, for several years, the most widely favored approach because of its relative simplicity, but it may be insensitive to single-base substitutions, especially if the change occurs near the middle of a large PCR fragment. Many laboratories now resolve PCR fragments by denaturing high-performance liquid chromatography on resin-based columns, which provides a sensitive, rapid, and inexpensive alternative to gel electrophoresis (63).

Protein truncation assays (64) are favored in several laboratories. Because BRCA1 and BRCA2 complementary DNA (cDNA) can be generated from blood lymphocytes, it is technically feasible to use a prokaryotic translation “cassette” to express the sequence in vitro and hence to demonstrate alterations in the length of a specific protein fragment. When only genomic DNA is available, the same technique can be applied to exon 11 (which encodes over half the protein for both genes) plus, for BRCA2, exon 10, which is also large (65). A number of permutations and variations of these basic techniques are currently in use in both research and diagnostic settings throughout the world, but the most efficient analytical process appears to be automated direct sequencing of all the exons and splice sites for both genes. This can detect the causal BRCA1 or BRCA2 mutation in more than 80% of all multicase families with breast cancer or breast and ovarian cancers, but the capital investment required to undertake such a screen on very large number of samples would probably be prohibitive, except on a commercial scale.

Large deletions in BRCA1, which may represent 10% or more of all mutations in some populations (32), can be detected by multiplex ligation-dependent probe amplification (MLPA) and related techniques (66,67). In a study of high-risk BRCA mutation-negative families, defined as four or more breast or ovarian cancers but wt BRCA1/2 results, Walsh found that 12% harbored a large genomic rearrangement missed by sequencing (68). This led to heightened pressure to overturn the BRCA1 and BRCA2 patent held by Myriad Genetics Corporation but only resulted in the laboratory offering additional testing for genomic rearrangements via quantitative PCR rather than MLPA. This is referred to as BART™, for BRCA rearrangement test.

The cost and the technical effort involved usually mean that strict criteria must be applied before a BRCA1 or BRCA2 mutation screen is embarked on. When a family belongs to a population group where “founder” mutations account for a substantial proportion of hereditary cases, an initial analysis limited to the recurring mutations is an attractive option. A reasonably robust

estimate of the likelihood that a germline mutation is present in one or the other gene can be derived simply from the (verified) family history. Thus, for example, if there are six or more individuals with female breast cancer, or just a single case of breast and ovarian cancers in the same patient, there is greater than 50% chance that a BRCA1 or BRCA2 germline mutation is present (69). This approach has been refined, for example, by development of a computer model, BRCAPRO (70), and empirically by Evans and colleagues (71), whose scoring system is based on the number, nature, and ages of onset of tumors in a given family. Both methods predict the likelihood of a BRCA1 or BRCA2 mutation and can be used to prioritize families for molecular testing. With increased volume of testing and testing of less “classic” hereditary breast–ovarian syndrome pedigrees, more mutations have been discovered than by the original high-risk cohorts. The generally accepted current indications for BRCA testing are noted in Table 89-2. Current testing guidelines vary slightly by professional society and country, but insurance companies in the United

States most often cite the National Comprehensive Cancer Network (NCCN) ([http://www.nccn.org/professionals/physician\\_gls/f\\_guidelines.asp](http://www.nccn.org/professionals/physician_gls/f_guidelines.asp)). Because of the availability of more targeted mutation testing at reduced cost for high-risk populations such as Ashkenazi Jewish individuals, testing should proceed in a stepwise manner based on the burden of the family history (Figure 89-3). In the future, particularly for BRCA1, initial screening may be in the molecular pathology laboratory on breast tumors, regardless of patient’s age or family history, in the same way that mismatch repair (MMR) gene defects are now screened for in colon cancers.

### 89.5.1 The Myriad Patent

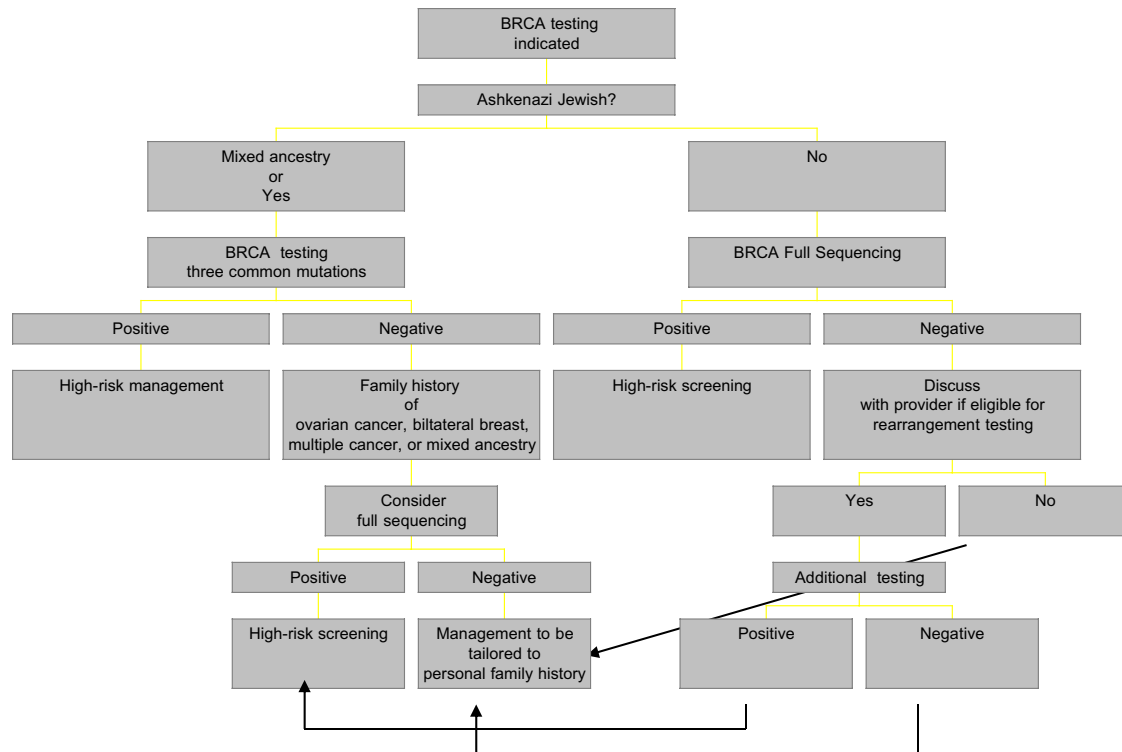

The construct of patenting a gene is one that garners great debate and fervor on both sides of the argument. Thousands of gene patents have been issued in the United States for the process relating to the sequencing of a particular gene. Though some require nominal licensing fees for use of the primers, most are open source. The notorious exceptions to this are the BRCA1 and BRCA2 gene patents held by Myriad Genetics Laboratory. Myriad has held exclusive rights to the commercial sequencing of the BRCA1/2 genes in North America and Europe since 1994. In May 2009, a group of plaintiffs led by the American Civil Liberties Union and the Public Patent Foundation challenged various aspects of the patent in a New York District Court case *Association for Molecular Pathology et al vs. US Patent and Trademark office*. In a landmark decision in March 2010, Judge Sweet overturned the Myriad patents, stating that isolated DNA was not materially different from that which exists in nature. Myriad immediately filed an appeal and there has been no practical changes in clinical practice in terms of availability of commercial testing in any other laboratory or changes in cost of testing (which at the end of 2011 approaches \$4000 for sequencing of both genes, with an additional cost of \$700 for testing of genomic rearrangements). In July 2011, a three-judge Federal Circuit Court reinstated the Myriad patent with a 2:1 opinion that cDNA in particular differs significantly from DNA in nature and is therefore eligible for patent under article 101 of the Patent Act, reversing the lower courts invalidation of product claims for BRCA genes and fragments. The judges, however, affirmed the lower courts ruling that Myriad’s methods for comparing mutant to normal sequences of the BRCA genes were *not* subject to patent protection. Both parties have since submitted petitions for further review, which had been denied by the Circuit Court of Appeals. It has been decided that the case will be heard by the US Supreme Court. Though the case is critical in terms of the broader issues in terms of whole-genome sequencing and feasibility of multiplex arrays in clinical testing, the patents on the BRCA genes will begin to expire in 2014.

**TABLE 89-2** Personal and Family History Indications for BRCA1/2 Testing

- Women with a Personal History of Breast Cancer with One or More of the Following:
  - Diagnosis at age  $\leq 45$
  - Diagnosis at age  $\leq 50$ , with  $\geq 1$  first-, second-, or third-degree relatives with breast cancer at age  $\leq 50$
  - Bilateral breast cancer or two breast primaries particularly if the first diagnosed at age  $\leq 50$
  - Diagnosis at any age, with  $\geq 2$  first-, second-, or third-degree relatives with breast and/or epithelial ovarian/fallopian tube/primary peritoneal cancer at any age
  - A male relative with breast cancer
  - A personal history of epithelial ovarian/fallopian tube/primary peritoneal cancer
- For an individual of ethnicity associated with higher mutation frequency (e.g. Ashkenazi Jewish, Dutch, Icelandic, Swedish, and Hungarian), no additional family history is necessary to test for the founder mutations
  - Triple-negative breast cancer before the age of 60 years
- Personal history of epithelial ovarian/fallopian tube/primary peritoneal cancer even if no other family history
- Personal history of male breast cancer even without any other family history
- Family history only:
  - First- or second-degree blood relative, meeting any of the above criteria
  - Third-degree blood relative with breast cancer and/or ovarian/fallopian tube/primary peritoneal cancer, with  $\geq 2$  close blood relatives with breast cancer (at least 1 with breast cancer at age  $\leq 50$ ) and/or ovarian cancer

NCCN guidelines are considered the most authoritative in the United States ([www.nccn.org/guidelines](http://www.nccn.org/guidelines), version 1.2011), but all US insurance companies have differing criteria for eligibility of testing. Indications noted above are minimum criteria recognized by most family cancer clinics and insurers. Refs: (12,149,274–276).

**FIGURE 89-3** Flowchart demonstrating stepwise approach for BRCA1/2 testing. Ashkenazi Jewish individuals are used as an example founder population, but any other high-frequency founder group would follow the same testing. Until genomic rearrangement testing is standard on all comprehensive tests, BART™ must always be considered as additional testing, though the yield is low in Caucasian populations. (From Morris, J. L.; Gordon, O. K. *Positive Results: Making the Best Decisions when You're at High Risk for Breast or Ovarian Cancer*. Prometheus Books: Amherst, NY, 2010. Reprinted with permission of Prometheus Books; [www.prometheusbooks.com](http://www.prometheusbooks.com))

### 89.5.2 Genetics and the Jews

The first major Jewish dispersion out of the land of Israel occurred after the Babylonian conquest and with it the fall of the First Temple in the year 586 BCE. This dispersion was to Mesopotamia, to the land now known primarily as Iraq. After several generations, some Jews returned to the land of Israel, but after the revolt against the Persians in the fourth-century BCE, many migrated further north toward the Caspian Sea and began the further gradual migration into Europe. Those who migrated north and west became the Ashkenazi Jews. The Jews who remained in Mesopotamia became the Persian Jews.

The next major upheaval and Jewish migration was the destruction of the Second Temple in the year 70 CE. At this time, the Romans shipped about 80,000 Jews as slaves to what is now Spain, south of Cordova. The descendants of these slaves became the Sephardic population. Until these Jews were expelled from Portugal and Spain in fifteenth century, there was no intermarriage between Sephardic Jews and Jews in other parts of the world.

The oldest of these founder mutations is 187delAG on *BRCA1* (previously designated 185delAG). It has been traced back between 2500 and 3000 years to around the time of the destruction of the First Temple (72). This mutation was carried north by the migration from

Mesopotamia through Europe. It occurs in about 1% of Jews in the United States and Europe. This mutation, interestingly, is also prevalent in certain Hispanic populations in northern Mexico and the southwest United States, areas that were settled by Spanish merchants. Historians believe that many of these settlers were *Conversos*, Jews who converted to Catholicism in response to the Inquisition and introduced this founder mutation into that community (73).

The second mutation, 6174delT in *BRCA2*, is the most prevalent of the three Jewish *BRCA* mutations, occurring in about 1.4% of Ashkenazi Jews. It does not appear in either Persian or Sephardic Jews. Because it does not appear in Persian Jews, the mutation must have occurred after the resettlement of the Ashkenazi Jews to Europe. This mutation likely originated in eastern Europe about 700 years ago, based on the mitochondrial DNA of carriers (72).

The third mutation is also on the *BRCA1* gene, although it is present in a far smaller percentage of Jews. Only about one-tenth of 1% of Ashkenazi Jews carry this third mutation known as 5382insC. This mutation is linked to another event in Jewish world history because it is also common among high-risk, non-Jewish women of eastern Europe, Russia, and Poland, in particular. Some call it the “pogrom” mutation and believe it was introduced into the Jewish community as a result of

pregnancies following conquests between the thirteenth and the nineteenth centuries. But like the 187delAG mutation that is common in certain North American Hispanic communities, it could be the reverse. Jewish individuals who converted to Catholicism may have perpetuated this mutation in the non-Jewish Polish population.

Together, these three mutations are found in 2.5% of so-called Ashkenazi Jewish women and men, in Israel, the United States, and Europe. The high rate of mutation carriers in the Jewish community is as a result of the cultural practice of a closed reproductive pool. Approximately 90% of American Jews are eastern European or Ashkenazi. Among those, 95% with a *BRCA* mutation carry one of these three founders, while about 5% of American Jews with a *BRCA* mutation carry one of the 2000 mutations, most of which are individually rare. These other mutations have been introduced because intermarriage and conversion have become more common, as well as due to the rare spontaneous new mutation.

## 89.6 RARE FAMILIAL SYNDROMES ASSOCIATED WITH INCREASED RISK FOR BREAST OR OVARIAN CANCER

The highly distinctive features of certain familial syndromes associated with cancer of the breast or ovary have served to emphasize genetic predisposition to these tumors, although the conditions (Table 89-3) are individually rare. Li–Fraumeni syndrome (LFS), for example, probably accounts for less than 5% of all heritable breast cancer cases, and the same is true of Cowden’s syndrome. Lynch syndrome may be the most common, though very rarely features breast cancer, and Peutz–Jeghers syndrome (PJS) very rare.

### 89.6.1 Li–Fraumeni Cancer Family Syndrome

The familial association of early-onset breast cancer with childhood soft tissue sarcomas, adrenal carcinomas, leukemias, or brain tumors (74,75) is certainly very striking and, compared with many other genetic syndromes, not rare. Historically, the fact that the tumors of close relatives may be managed at different specialist centers has perhaps militated against more widespread recognition of the hereditary nature of the condition: affected families have often been found by systematic surveys, for example, of childhood brain tumors or sarcomas, rather than by direct referral to a geneticist from a breast cancer surgeon or pediatric oncologist (76).

When the association between LFS and constitutional mutation in the *p53* gene was reported in 1990 (2,3), it seemed that this particular aspect of familial breast cancer was adequately explained. A very similar spectrum of tumors is also observed in *p53*-deficient transgenic mice (77). However, in a considerable number of “classic”

Li–Fraumeni families, *p53* mutations can be extremely difficult to find (76,78). Some germline mutations involve parts of the gene outside the “hot-spot” regions of exons 5–8, including splice sites and regulatory elements, and partial or whole-gene deletions (79,80). The mutation may be in another gene, *CHEK2*, that participates in an analogous DNA damage response/cell cycle arrest pathway (81).

The clinical definition of the LFS has been widened to encompass germ cell tumors and Wilms’ tumor. Other cancers that may also arise from constitutional *p53* mutations include those of lung, prostate, and pancreas, as well as malignant melanoma. Williams and Anderson (82) concluded that more than 90% of “gene carriers” in Li–Fraumeni kindreds would develop a cancer by age 70, but this study was based on families ascertained, at least to some extent, on the basis of high penetrance.

**TABLE 89-3 Cancer Syndromes with Clinical Features**

Syndrome	Features	Gene
Cowden	Multiple hamartomas of skin and oral mucosa, trichilemmoma, 35% have gastrointestinal (GI) hamartomas, limited malignant potential, autosomal dominant inheritance, breast cancer, uterine cancer, and 10% of both sexes develop thyroid cancer	PTEN
Li–Fraumeni	Classically, early-onset breast cancer in affected females and an excess of childhood sarcomas, acute leukemias, brain tumors, or adrenal cancers. Melanoma, Wilms’ tumor, and germ cell tumors may also be part of the syndrome, which can be widened to include “Li–Fraumeni-like” families. Multiple primary tumors are characteristic	<i>p53</i> <i>CHEK2</i>
Muir–Torre variant of HNPCC	Skin lesions (keratoacanthomas and sebaceous adenomas) associated with ovarian, uterine, colorectal, and duodenal cancers and some excess of breast, bladder, and esophageal cancers	MLH1 MSH2 MSH6 PMS2 EpCAM
PJ	Hyperpigmentation, mainly in and around the mouth. Multiple hamartomatous polyps, particularly of the small intestine, breast, and ovarian sex cord tumor (SCT)	STK11

All individuals with a personal or family history of breast cancer and other malignancies should have a clinical examination to evaluate for the possibility of Cowden syndrome or PJS. Trichilemmomas are pathognomonic for Cowden. Individuals with sebaceous adenomas and/or keratoacanthomas and endometrial or colon cancer should be assessed for Muir–Torre. These cutaneous lesions alone, however, are not an indication for testing.

More recently, *TP53* mutations have been found in families not meeting the original strict clinical diagnosis criteria, and a Li–Fraumeni-like syndrome with more broadly inclusive criteria has emerged (83). These are referred to as the Eeles, Birch, and Chompret criteria (Table 89-4). The breast cancer risk in those with LFS is highly elevated, perhaps as high as 50–60% by age 45 (84,85). Mutations in *TP53* have been identified in 4% of women diagnosed with breast cancer at younger than 30 years, half of which were *new* rather than inherited mutations (84). In 2009, Gonzalez reported on

525 diagnostic samples evaluated for p53 mutations. About half of those tested who met classic LFS were found to have a detectable mutation. Breast, brain, sarcoma, and adrenocortical carcinoma (ACC) were the core cancers seen in all positive cases. However, the Chompret criteria (very young age of onset or multiple primaries in proband) was also sensitive in predicting mutations (79).

So, though a number of historic studies have reported that only 1% or less of unselected breast cancers can be attributed to constitutional p53 mutations, it is clear that this figure is considerably higher for patients who have suffered two primary tumors (e.g. including breast or germ cell cancer), particularly if one of these presented at an early age, even if there is no obvious LFS in the patient's family history, or if the proband has breast cancer at younger than 30 years, ACC, or a choroid plexus tumor (2,79,80).

**TABLE 89-4 Testing Criteria for LFS**

Classic LFS Criteria:
– Combination of an individual diagnosed at age <45 with a sarcoma
AND
– A first-degree relative diagnosed at age <45 with cancer
AND
– An additional first- or second-degree relative in the same lineage, with cancer diagnosed at age <45 or sarcoma at any age
Li–Fraumeni-like syndrome criteria:
Birch:
• Combination of an individual diagnosed with a childhood tumor or sarcoma, brain tumor, or adrenocortical carcinoma diagnosed at age <45
AND
• A first- or second-degree relative with a typical LFS tumor at any age
AND
• Another first- or second-degree relative with cancer diagnosed at age <60 (76)
Chompret:
• An individual with a tumor belonging to the LFS tumor spectrum (soft tissue sarcoma, osteosarcoma, premenopausal breast cancer, brain tumor, adrenocortical carcinoma, leukemia, or lung bronchoalveolar cancer) before the age of 46 years
AND
• At least one first- or second-degree relative with a LFS tumor before the age of 56 years or multiple tumors
OR
• Personal history of multiple tumors (except multiple breast tumors), two of which belong to the LFS tumor spectrum and the first of which occurred before the age of 46 years
• Personal history of adrenocortical carcinoma or choroid plexus tumor
Eeles:
• Two first- or second-degree relatives with LFS-related malignancies at any age
Early-onset breast cancer:
– Individual with breast cancer at age <30, with a negative <i>BRCA1</i> and <i>BRCA2</i> test, especially with a family history of sarcoma, brain tumor, or adrenocortical carcinoma

Criteria have widely varying sensitivity, with Chompret being the most predictive and Eeles the least. Cancers associated with LFS include, but are not limited to, premenopausal breast cancer, bone and soft tissue sarcomas, acute leukemia, brain tumor, adrenocortical carcinoma, colon cancer, early-onset of other adenocarcinomas, or other childhood cancers. Refs: (2,79,80,83–85).

### 89.6.2 Diffuse Hereditary Gastric Cancer Syndrome

E-cadherin gene mutations are often found in sporadic cancers and are frequently used to distinguish histologically lobular breast cancer from ductal carcinoma. Hereditary diffuse gastric cancer is caused by germline mutations in *CDH1*, and women carriers are at greatly increased risk for lobular breast cancer. The gene is inherited as an autosomal dominant disorder and carries an almost 90% risk for diffuse gastric cancer (*limitis plastica*) and up to 40% risk for breast cancer in women and a 67% risk for gastric cancer in men (86,87). Pedigrees with lobular carcinoma of the breast and “stomach cancer” should be assessed for the possibility of an E-cadherin mutation. However, adenocarcinoma of the stomach is the most common form of gastric cancer and is not associated with *CDH1* mutations but is rather associated with *Helicobacter pylori* infections and chronic reflux.

### 89.6.3 Peutz–Jeghers Syndrome

PJS is a multiple cancer susceptibility syndrome that also has clinical features. PJS, which is due to mutations in the serine-threonine kinase 11 (*STK11*) gene, causes multiple colon hamartomas, distinctive pigmented macules of the mucocutaneous tissue, plantar and palmar volar surfaces, and a predisposition to cancer of the small and large intestines, breast, and pancreas. *STK11* is a tumor suppressor gene localized to 19p13.3 and is also known as *LKB1* (88). In a recent meta-analysis review of 20 studies, the most common malignancy seen was colorectal, followed by cancer of the breast and the small bowel and stomach. Other gynecologic malignancies seen are ovarian cancer, which characteristically is a stromal sex-cord tumor and not an epithelial tumor (as in *BRCA*) and cervical cancer. In this meta-analysis of the worldwide experience, the average age of cancer was 42 years,

and women had much higher overall RR for malignancy (89). The frequency estimations widely vary from 1 in 8000–200,000, in part because the clinical syndrome is often overlooked in the differential diagnosis of early-onset breast cancer. Notably, early and bilateral breast cancer is the hallmark of PJS. STK11 is the only gene associated with PJS, and molecular testing can now identify virtually all mutations, thus making genotyping very useful to confirm or exclude a suspected diagnosis (88).

#### 89.6.4 Cowden's Syndrome/PTEN

Cowden syndrome (CS) is a cancer predisposition syndrome arising from mutations in the *PTEN* gene, associated with increased risk for breast, thyroid, and uterine cancers. This condition, like all the others discussed thus far, is inherited as an autosomal dominant disorder. Distinctively, it is associated with the development of hamartomas and benign tumors in the skin and the internal organs and hence the alternative name “multiple hamartoma syndrome” (90). An increased incidence of breast cancer in affected women has long been demonstrated and, indeed, overlaps with two other allelic inherited disorders, Lhermitte–Duclos disease and Bannayan–Zonana syndrome (also known as Bannayan–Riley–Ruvalcaba syndrome), suggesting that all three carry significant risks for malignancy of thyroid, brain, and endometrial, as well as breast (91,92). The causal locus for all three conditions was subsequently mapped to chromosome 10q23, and germline mutations were then identified in a number of affected families, in a gene variously known as PTEN (phosphatase and tensin homolog) or MMAC1 (mutated in multiple advanced cancers) or TEP1 (tumor growth factor  $\beta$ -regulated and epithelial cell-enriched phosphatase) (93,94). The lifetime risk for breast cancer is estimated at 25–50%, the most common malignancy in CS (95), and for endometrial at 5–10% (96).

Diagnostic criteria are sorted into pathognomonic features, major and minor criteria (Table 89-5). Recently, after analysis of over 3000 pediatric and adult patients referred for PTEN testing, a Cleveland Clinic PTEN scoring system was created. This weighted system recommends testing for scores above 10, or a pretest probability of a mutation of 3% (97). Diagnosis is made with a single pathognomonic feature (Lhermitte–Duclos disease or the mucocutaneous lesions: facial trichilemmomas, acral keratosis, or papillomatous papules). Major criteria must include macrocephaly (defined as a head circumference greater than 97th percentile) and endometrial, breast, or non-medullary thyroid cancer. Combinations of minor criteria exist, but the likelihood of detecting a mutation is very low unless major criteria are met (98). Nevertheless, it is quite probable that the diagnosis is overlooked in some breast cancer families because the defining signs and symptoms can be subtle. Breast cancer in patients with Cowden's syndrome may be preceded by a long history of benign proliferative disease (91,99).

**TABLE 89-5** Diagnostic Criteria for Cowden Syndrome

Major Criteria for Cowden Syndrome	Minor Criteria for Cowden Syndrome
<ul style="list-style-type: none"> <li>Breast cancer</li> </ul>	<ul style="list-style-type: none"> <li>Other thyroid lesions (such as adenoma, nodule, goiter)</li> </ul>

<ul style="list-style-type: none"> <li>Two or more major criteria (one must be macrocephaly) OR</li> </ul>	
<ul style="list-style-type: none"> <li>Three major criteria, without macrocephaly OR</li> </ul>	
<ul style="list-style-type: none"> <li>One major and three or more minor criteria (may include an additional major criteria in place of one of the three minor criteria) OR</li> </ul>	
<ul style="list-style-type: none"> <li>Four or more minor criteria</li> </ul>	

The combination of mucocutaneous lesions and breast cancer should always prompt evaluation for Cowden syndrome. The online scoring system is a helpful tool in determining pretest probability of a mutation. Tan, M.H., et al. A Clinical Scoring System for Selection of Patients for PTEN Mutation Testing Is Proposed on the Basis of a Prospective Study of 3042 Probands. *Am. J. Hum. Genet.*, 2011, 88(1), 42–56.

Refs: (90,92,97,98).

The PTEN gene behaves as a classic tumor suppressor. The wt allele is generally lost in tumor tissue from mutation carriers, and unlike BRCA1 or BRCA2, somatic mutations in PTEN are found in a substantial proportion of sporadic breast, prostate, endometrial, and other cancers (100,101). It has nine coding exons, and both germline and somatic mutations appear to be distributed throughout the length of the gene (94). Various deletions have been reported (102) and 2% of patients with a clinical diagnosis of Cowden syndrome have mutations in the promoter region of the PTEN gene (103). Most recently, a promoter mutation in KILLIN gene, which is adjacent to PTEN and also regulates PTEN function, was found among a subset of patients with CS and Cowden-like

syndrome. *PTEN* and *KILLIN* share the same transcription start site but are transcribed in opposite directions, and germline methylation of the 10q23.31 bidirectional promoter CpG island silences *PTEN* or *KILLIN*, or the translation of both (104). These patients appear to have an even greater risk for breast cancer and a significant risk for renal carcinomas.

### 89.6.5 CHEK2

*CHEK2* produces a checkpoint kinase protein, activated in response to radiation and other agents that cause breaks in the DNA. *CHK2* (or *CHEK2*) functions broadly comparable to *ATM*, has been implicated in some instances of LFS and is considered a low-penetrance breast cancer gene. *CHEK2* was dubbed the breast-colon gene as it appeared to increase the risk for breast and colon cancers in both men and women, as well as prostate cancer in men (105). A common deleterious variant in *CHEK2*, 1100delC, is predicted to result in a truncated version of the repair protein. This variant is found in approximately 1.4% of Caucasians of northern European descent (106) and is associated with a twofold to threefold increased risk for breast cancer (CHEK consortium 2004). Whereas, one variant, T59K, appeared to be associated with cancer (particularly breast cancer) in Icelandic patients (107). *CHEK2* is now considered a common “moderate” risk gene for breast cancer. Several additional studies implicate a mutation in *CHEK2* as a significant risk for bilateral breast cancer and may increase cancer risk from the effects of ionizing radiation such as those found in radiation therapy and computed tomography scans (108). Multiple studies have found no interaction between *CHEK2* variants and *BRCA1* and *BRCA2* mutations (106,109), though it is likely to interact with other genes because the cancer risk varies depending on the extent of the family history, with at-risk children of mothers with bilateral breast cancer having higher lifetime risk than those with no family history.

### 89.6.6 PALB2

*PALB2* is a partner and localizer of *BRCA2*. The *PALB2* gene was originally identified as producing a *BRCA2*-interacting protein and thought to be a modifier gene in families with *BRCA2* mutations. Additionally, it is called *FACN* and functions within the Fanconi anemia pathway, with biallelic mutations resulting in a similar phenotype as biallelic *BRCA2* carriers (38). However, several mutations in *PALB2* have been associated independently with an increased risk for breast and pancreatic cancers. A founder mutation, 1592delT, has been reported in Finland among high-risk families who are *BRCA*-negative (families without any *BRCA* mutations). The cancer risk varies among studies, from moderate-like in *CHEK2* to mimicking *BRCA*, with up to a 40%

lifetime breast cancer risk (110). Monoallelic germline mutations have been implicated in both familial breast and pancreatic families (111,112). There has been a significant disparity over the proportion of familial breast and pancreatic cancers accounted for by *PALB2*, and it may be an ethno-regional issue. In a large series from the University of Washington, 3.2% of subjects unselected for ethnicity but *BRCA*-negative were found to carry a mutation, but none of 172 Ashkenazi Jewish individuals has the mutation. The age and distribution of cancers (female and male breast and pancreatic cancers) were similar to *BRCA2* (113). Hofstadter also found about a 2% frequency among breast/pancreatic families, with frequency not enriched by pancreatic history (114). However, in a Dutch series of 110 *BRCA1/2*-negative hereditary breast-ovary families, one recurrent mutation was found in a male breast cancer, and the authors concluded that *PALB2* does not explain *BRCA*-negative hereditary breast-ovarian cancer (HBOC) (115). *PALB2* is now commercially available for testing and should be certainly considered for hereditary pancreatic cancer families as well as patients with breast and pancreatic family history, though it remains to be clarified whether there are particular ethnic groups in whom it is not likely to be causative.

## 89.7 LOW-PENETRANCE BREAST CANCER GENES

Estimates of genetic risk for breast cancer derived from segregation analysis show that only a minority of women at increased risk belong to families in which the incidence of disease is so high as to generate a striking “cancer family” pedigree (6,116). About two-thirds probably carry mutations that confer a lifetime risk of approximately 25–40%. If such a mutation is in an autosomal gene, it is most unlikely to generate a spectacular cancer pedigree as the chance of an affected woman having an affected mother or sister (in an average-sized family) will be less than 50% (11). In the early 2000s, a great number of association studies were published as candidates for polymorphisms conferring low levels of risk or protection from breast cancer. For example, a review of reported studies in this field identified approximately 13 polymorphisms in 10 genes that had been associated with breast cancer at a 5% significance level (117) and that one *BRCA1* variant (Gln356Arg) may actually be protective against breast cancer (118). The many polymorphisms within *BRCA1* and *BRCA2* are obvious candidates for low-penetrance cancer genes, but no convincing evidence has been presented for such a role. Most of these associations have not been sustained by larger associations or genome-wide studies.

Ataxia-telangiectasia (A-T) is an autosomal recessive disorder, characterized by immunologic defects, ocular and cutaneous telangiectasia, and progressive cerebellar ataxia from early childhood (119). Homozygotes have

an increased susceptibility to cancers, particularly leukemias and lymphomas (120,121). The primary defect seems to be in one of the pathways of DNA repair following ionizing radiation or radiomimetic agents, and cells from homozygotes are abnormally sensitive to ionizing in vitro (122). The A-T locus was mapped to chromosome 11q22–23, and the gene (ATM) was cloned in 1988, one of the earliest cancer genes identified (123). Reference has already been made to the evidence that BRCA1, BRCA2, and certain other genes involved in the detection of—and cellular response to—DNA damage may form an interactive chain, with ATM as an important member. Although A-T homozygotes are rare (about 1 in 40,000 individuals at birth), heterozygotes comprise about 1% of the population. Several epidemiologic studies in the United States, the United Kingdom, and Scandinavia have suggested that female heterozygotes have a risk for breast cancer three to five times greater than the age-matched controls (124,125), but this has not been upheld in a large, collaborative, multicenter survey (126). Overall, therefore, it seems that the gene may be responsible for a limited number of early-onset cancers but not for many striking family clusters.

It is far from clear whether increased radiosensitivity plays any part in the cancer susceptibility of A-T or CHEK2 heterozygotes and, in particular, whether the radiation dose associated with mammography (about 2 mGy per film in traditional nondigital mammograms) might be sufficient to exacerbate the situation. On the one hand, data from atomic bomb survivors suggest that doses of around 100 mGy are required to demonstrate any increase in breast cancer risk and that sensitivity is greatest around adolescence, declining considerably by age 40. On the other hand, conventional in vitro tests of sensitivity to radiation and other clastogens give some indication that A-T heterozygotes are abnormally susceptible to chromosome breakage, and a threshold radiation dose is difficult to define (127,128). Studies, using blood lymphocytes arrested in the G2 phase of the cycle, appear to demonstrate radiosensitivity in about 10% of unselected individuals, whereas approximately 40% of breast cancer patients fall into the abnormally sensitive range (129). The relatively high frequency of the sensitive phenotype suggests that A-T heterozygosity accounts for very little of it. Nevertheless, radiation sensitivity, as measured by this assay, is inherited as a Mendelian dominant or codominant trait (130). Furthermore, one study (131) found that breast cancers arising in patients who show high G2 sensitivity tend to show favorable prognostic features reminiscent of the characteristic of non-BRCA1 and -BRCA2 familial breast cancers (52). The (currently unknown) gene or genes responsible may well contribute substantially to the total genetic risk for breast cancer. However, systematic studies to try and determine how much breast cancer in the population is due to ATM mutations have been conflicting. The WECARE—Women's Environment, Cancer, and

Radiation Epidemiology—study is currently ongoing and addresses the question of whether routine low-level radiation exposure as in mammography increases breast cancer risk in ATM carriers and other specific populations (132).

## 89.8 ASSOCIATION STUDIES AND GENOMICS OF BREAST CANCER

Since 1997, there have been numerous association studies identifying polymorphisms in genes involved in breast cell proliferation, hormone receptor response and metabolism. For example, in one study (133), a polymorphism of the Cyp17 gene was significantly more common in breast cancer patients than in controls. Subsequent surveys found no such association for breast cancer in women, although it does appear to hold true for male breast cancers (134) and may be attributed to variation in activity of the steroid-metabolizing enzyme encoded by CYP17, with consequent small changes in estrogen level (133). Polymorphisms in CYP17 have been incorporated into the proprietary breast cancer risk algorithm known as OncoVue™, which combines the effects of multiple single nucleotide polymorphisms (SNPs) and stratifies risk based on menopausal status (135).

Many published studies have investigated possible interactions between major susceptibility genes such as p53, BRCA1, or BRCA2, and minor modifying genetic characters that could influence the penetrance of the cancer trait or its severity (e.g. age of onset and types of cancer observed). An SNP in the RAD51 gene was over-represented among women with breast cancer who carried the Ashkenazi Jewish BRCA2 mutation, compared with unaffected carriers; no such association was found for BRCA1 mutations, nor for CHK2 or ATM variants (136,137). RASSF1A is a tumor suppressor that regulates cell cycle progression and apoptosis. It is methylated in 50% of breast cancers. More recently, in a group of 138 BRCA1/2 carriers, the A133 polymorphism in RASSF1A has been shown to be associated with earlier age of onset of breast cancer (138). There have been a large number of investigations into the role of one specific variant in RAD51, as it relates to sporadic breast cancer and role as a modifier of BRCA-related breast cancer. There are much conflicting data in the literature regarding the impact of an SNP of RAD51, 135G>C (rs1801320). There have been several recent meta-analyses, in both BRCA carriers and the other in sporadic breast cancer. In sporadic cancer, the 135 variant was not associated with increased risk alone, but may be in a recessive model and not in a heterozygous state (139). Zhou conducted an even larger meta-analysis and found an increase in risk overall, but among the subset analysis, only the homozygous variant had an influence on risk in BRCA2 carriers (103).

However, to date, none of these SNP associations have provided any meaningful clinical utility (140,141), even

though the RAD51 SNP was briefly commercially available as a BRCA breast cancer modifier test (DeCode™ Genetics, 2009). The CIMBA and EMBRACE consortium have been investigating genome-wide associations of breast cancer penetrance in BRCA carriers. A cohort of 2825 BRCA1 carriers underwent haplotype analysis, and specific haplotypes in ATM, CTIP, NBSI and TOPBP1 were associated with increased breast cancer risk, whereas BRIP1 and RAD50 with decreased risk. There was no association with BRCC36, ABRA1, MRE11A, PALB2, RAD51 and RAP80 with regard to breast cancer, but ABRA1, BRCC45 and RAP80 haplotypes were associated with ovarian cancer risk. Authors conclude that proteins that interact with BRCA1 modify the cancer risk in BRCA1 carriers (142).

Easton et al. have been pioneers in genome-wide studies of breast cancer, and along with researchers from Iceland, they identified seven SNPs through a genome-wide association study (GWAS) of 225,000 European Caucasian women (143). Additional studies are regularly published as the mapping becomes more refined and different cohorts are evaluated. The risk in most women is felt to be the cumulative effect of multiple, common genetic changes, each one of which has a small impact on breast cancer risk (144). Only a single common coding variant in CASP8, which was originally found via a candidate gene association study, was also seen as a risk allele in Easton's GWAS (145).

In an effort to estimate individualized risk, Pharoah modeled that these original seven SNPs would only have a significant impact on 63 of every 10 million women: 56 of whom will have all of the low-risk alleles (SNP changes associated with lower breast cancer risk) and seven of the 10 million women will have all of the high-risk alleles. Pharoah and Easton estimated that those with all of the low-risk changes will have a lifetime breast cancer risk of 4.2% and those with all of the high-risk changes will have a lifetime risk of 23% (using 9.4% as the population risk percent). All others will have some combinations of high- and low-risk alleles—2187 possible combinations of these SNPs—and it is not clear what risk those combinations confer (141). The goal is that when the majority of protective and risk SNPs are identified, a true genomic prediction of risk will be attainable. Nonetheless, commercial companies are already marketing tests based on some or all the SNPs that have already been identified.

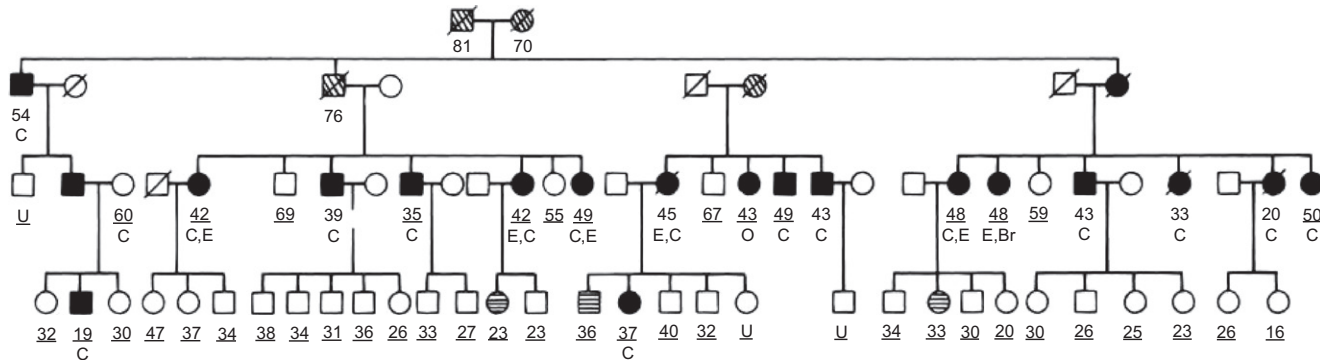

There are multiple SNP-based genomic tests currently available. Some are based on various combinations of SNPs and other tests combine SNP information with other risk factor data, such as family history and reproductive history (135,146). These models are being validated in terms of improvements in predicting individual risk above the Gail model alone, which looks only at age, family history, and reproductive risk factors (147–149). More recently, Mealiffe assessed the validity of the seven common SNPs noted in the Caucasian

GWAS, mentioned noted above, combined with the standard Gail-calculated breast cancer risk in several 1000 cases and controls from the Women's Health Initiative Study. Subjects were white, non-Hispanic postmenopausal women. Their results, like others, found that the SNP risk score was nearly independent of the Gail score, which has also been seen by Jupe et al. using other SNPs. Based on the assumption that the Gail risk and each of the SNPs are independent, the combination of the SNP and Gail scores resulted in a slight improvement in risk prediction, with greatest improvements for those whose Gail score alone was in the intermediate risk category, defined as an empiric 5-year risk of 1.5–2.0% (150). Similar results were found in a much larger analysis, with the authors concluding the reclassification of a substantial proportion of subjects from an intermediate risk category to a higher or lower level of risk (151).

## 89.9 HEREDITARY NONPOLYPOSIS COLORECTAL CANCER SYNDROME (OR LYNCH SYNDROME)

Several human homologs of the yeast or bacterial MMR genes (152) have now been mapped, sequenced, and implicated in familial cancer syndromes. These genes, designated hMLH1, hMSH2, hMSH6, hPMS1, and hPMS2, are located on chromosomes 3p21–23, 2p15–16, 2p, 2q31–33, and 7p22, respectively (153). The characteristic homozygous mutant phenotype is instability of microsatellite repeats owing to incomplete editing of replication errors, hence the term replication error repair or microsatellite instability (MSI) syndromes. Such instability is found only in tumors in which the wt allele has been inactivated. Thus, the mutations appear to be recessive at the cellular level. However, in contrast to many other situations in which a recessive tumor suppressor is involved, loss of heterozygosity (LOH) at the relevant locus is rare (154).

Most individuals carrying a mutation in one of these genes have been identified by screening for the hereditary nonpolyposis colon cancer (HNPCC) phenotype, originally subdivided by Lynch into types I and II. Type II is now synonymous with Lynch syndrome or HNPCC and encompasses other malignancies—particularly endometrial and ovarian—in addition to colon cancer, in which the tumors are predominantly in the right colon, in contrast to sporadic cancers that occur predominantly in the left colon. There is a clear excess of other cancers, notably endometrial, which is often the presenting cancer in female carriers (Figure 89-4). However, because the original families are large and were selected for a high incidence of cancers, some of the tumors noted in the pedigrees may be unconnected with the constitutional mutations demonstrated. In particular, whether breast cancer occurs more frequently than would be expected from the relevant population incidence is still under debate, and although overall breast cancer does not appear as a consistent cancer in

**FIGURE 89-4** Pedigree showing features of HNPCC (Lynch type 2 family cancer syndrome), associated with mutation in the replication error repair gene hMSH2 on chromosome 2p. Filled symbols = persons with cancer. Horizontal stripes indicate persons with colorectal adenoma. Letters signify tumor sites: C, colon or rectum; E, endometrium; U, unknown; O, ovary; and Br, breast. (From Peltomäki, P.; Aaltonen, L. A.; Sistonen, P., et al. *Genetic Mapping of a Locus Predisposing to Human Colorectal Cancer*. Cell **1993**, 75, 1215–1225.)

HNPCC, there are clearly some families with a significant overrepresentation of breast cancers (155,156).

In unselected series, very little evidence has been obtained of MSI in either breast or gynecologic tumor, contrasting with rates of approximately 15% reported for “sporadic” colon cancers (157,158). MSI is an inconsistent feature of MMR-related hereditary endometrial and ovarian cancers, making it a poor pathologic screen for HNPCC (159). Immunohistochemistry (IHC) testing is a widely and commercially available antibody assay that can identify intact protein in paraffin-embedded tumor blocks. In colon tumors, MSI and loss or absence of IHC staining are strongly correlated (160) and have largely replaced MSI as first-tier screening for MMR gene defects. Significant attention has focused on the universal screening of colon tumors for evidence of MMR defects to identify germline mutations in individuals who might otherwise not come to clinical attention and it has been endorsed under the Center for Disease Control’s independent panel, the Evaluation of Genomic Applications in Practice and Prevention Working Group recommendation statement (161,162).

### 89.10 ENDOMETRIAL CANCER

As already discussed, the association of colon and endometrial cancers is a striking feature of both HNPCC and Cowden’s syndrome (94,163). Endometrial cancer is often the presenting cancer in women with HNPCC, with upward of 60% lifetime risk and earlier age of onset than the colon cancer (164). The original Bethesda guidelines for screening of HNPCC in 1996 recommended screening six patient populations, two of which were gynecologic: early-onset endometrial cancer and two Lynch cancers and synchronous ovarian and endometrial cancers. Subsequent findings suggested that endometrial cancers are associated particularly with mutations in hMSH6 (165), but more comprehensive investigations have demonstrated both gynecologic malignancy risk and colon cancer risk in MSH6 mutations, with some

families demonstrating substantial endometrial and ovarian cancers (166). Endometrioid adenocarcinomas of the endometrium and synchronous endometrial and ovarian cancers are a hallmark of HNPCC-related gynecologic tumors, and although they tend to occur earlier than sporadic endometrial cancer (mean age of 42 years in the International Collaborative Group on HNPCC’s cohort), the tumors are otherwise generally well differentiated and tend to be early stage when diagnosed (167). Hampel and colleagues evaluated the feasibility of screening all the endometrial cancers with MSI testing and comparing that to IHC testing as a screen. They found that among 543 newly diagnosed cases of endometrial cancer, at least 1.8% had a confirmed mutation in one of the four MMR genes. Seven of 10 did not meet any criteria for HNPCC testing and six were older than 50 years. In addition, a number of subjects had missense mutations; thus, their functional status could not be confirmed (159). In a study of early-onset endometrial cancers (before age 45) and synchronous primary endometrial and ovarian cancers, 12% of patients had a mutation identifiable in MLH1, MSH2 or MSH6, and methylation was seen in three patients with MHL1-absent stain, but no mutation was detected, supporting the universal screening for all the early-age or synchronous tumors with IHC (168).

PMS2 mutations are emerging as another potentially significant proportion of HNPCC cases, but the families described vary immensely in terms of spectrum of malignancy and ages of onset, from much milder presentations overall to a few outliers with profound cancer family histories (169). Finally, epithelial cell adhesion molecule (EpCAM) gene is upstream of MSH2, and in recent years, it has been shown to be a novel mutational mechanism causing Lynch syndrome by epigenetic inactivation of MSH2. It has been shown recently that loss of protein expression by IHC testing of the EpCAM protein correlates with a heterozygous deletion of the gene (170), and this may lead to changes in pathology department screening to include IHC for EpCAM in MSH2-absent tumors.

Small excesses of endometrial cancer have also been recorded in epidemiologic studies among relatives of patients with ovarian or breast cancer (171,172). For most of the published studies, it is not possible to quantify the contribution of families with HNPCC or Cowden's syndrome to the data sets, and endometrial cancer has been reported in cohorts of BRCA1 and BRCA2 mutation carriers, with controversy whether those genes also confer an increased risk (173,174). For example, endometrial cancer was recorded in several of the Icelandic families with BRCA2 999del5 mutations (175), and in an Israeli series of uterine papillary serous carcinoma, a distinct and aggressive type of endometrial cancer, four of 20 women were BRCA carriers (18), and it has been hypothesized that perhaps some of the primary peritoneal cancer seen in BRCA carriers who had previously undergone prophylactic oophorectomy arose from the fallopian tube still implanted within the uterine wall (176). Because of this, for a number of years, recommendations had shifted to consider total hysterectomy at the time of salpingo-oophorectomy. Several large series of endometrial cancers, even papillary serous endometrial cancer, did not show an excess of BRCA mutations (19,177).

Endometrial cancer risk is also important because one option being considered in an attempt to reduce the risk for breast cancer in BRCA1 and BRCA2 family members is prophylactic tamoxifen (178). Endometrial cells respond to tamoxifen by enhanced proliferation, and there is evidence of an increased incidence of endometrial cancer in patients exposed to the drug (179–181).

Other tumors of the uterus (principally sarcomas) are rare and not known to have any underlying hereditary basis.

### 89.11 FAMILIAL OVARIAN CANCER

Family clustering of ovarian cancer, in the absence of any other cancers, is rare. Much more common is the association with breast cancer, and even large “ovarian-only” cancer families ultimately demonstrate breast cancer when the current generation used oral contraception or underwent preventive surgery (83). There is no evidence for any major gene predisposing strongly to ovarian cancer, other than BRCA1 and BRCA2 and rarely in HNPCC (without the more prevalent colon and endometrial cancers). In families with PJS, the ovarian tumors are not epithelial tumors but gonadal sex cord tumors. Among families with breast and ovarian cancers, constitutional mutations in BRCA1 outnumber those in BRCA2 by about 4:1. Together, constitutional mutations at these loci account for at least 5% and possibly as much as 15% of all ovarian cancers in most developed countries (7,116,182).

It is clear that the great majority of familial tumors are serous adenocarcinomas, carrying a very poor prognosis (183,184). Borderline tumors do not appear to form part of the BRCA1 or BRCA2 mutation phenotype, nor do

germ cell tumors. Although there are occasional reports of familial clusters of teratoma, arrhenoblastoma, or dysgerminoma, the question of whether these are truly genetic remains open. In a few instances, constitutional mutations in p53 may be suspected (185). A most important finding, in relation to management of familial ovarian cancer, is that in BRCA1 and BRCA2 mutation carriers, there is a substantial risk that the primary ovarian tumor may arise in the fallopian tube or diffusely within the peritoneum (186,187).

The mean age of onset for familial ovarian cancer is lower than that for sporadic cases, but the effect is less clear-cut than that for breast cancer, and familial ovarian cancers rarely occur in patients younger than 40 years (174). Estimates of age-specific penetrance for breast or ovarian cancer in BRCA1 and BRCA2 mutation carriers are shown in Table 89-5. The ovarian cancer risks associated with germline mutations in BRCA2 are, in general, less than half of those applying to BRCA1 mutation carriers. As discussed earlier, there initially appeared to be a phenotype/genotype correlation, with an “ovarian cancer cluster region” being located in the central portion of the gene (188), but this has also been largely discounted more recently (189,190).

Alternative explanations for differential risks for breast or ovarian cancer in BRCA1 or BRCA2 families include the effects of modifying genes and environmental factors (7). The use of oral contraception may have played a part in shifting the risk from ovarian cancer toward breast cancer over the course of the past 20 years (191), and this may be relevant in the few large families with ovarian cancer mentioned earlier, in which breast cancers have occurred only recently. Nevertheless, there remain striking and unexplained instances of BRCA1 mutation-bearing families with multiple cases of ovarian cancer but no (or few) breast cancer, although the germline mutations are identical to those carried by several other families with more typical distribution of tumors. Further work, including, for example, twin studies, is urgently required to cast light on this clinically important issue.

The lifetime risk for ovarian cancer in individuals with a MMR gene defect is estimated at 11% (168). Synchronous colon and ovarian cancers should always prompt consideration of Lynch syndrome. However, as colon cancer frequently metastasizes to the ovary, pathologic confirmation of multiple primaries is crucial in risk assessment. Screening ovarian tumors for IHC analysis of the MMR genes is possible, but the reliability of IHC in this cell type is unknown, and as discussed earlier, MSI testing is insensitive in HNPCC-related ovarian cancer (159).

#### 89.11.1 Low-Penetrant Genes for Ovarian Cancer

Epithelial ovarian cancer has a major heritable component, even stronger than that for breast cancer, but the aforementioned single genes (BRCA1/2, MLH1, MSH2,

MSH6, PMS2) explain less than half of the familial risk (87). Women with a first-degree relative with ovarian cancer have a threefold increased risk of developing the disease (192), though probably about half of this observed risk is explained by BRCA and MMR gene mutations. Genome-wide studies have thus attempted to identify new regions of risk and low-penetrant polymorphisms that predispose to ovarian cancer. In a three-stage genome-wide study conducted with the Ovarian Cancer Association Consortium throughout the United Kingdom, the United States, and Australia, 12 polymorphisms reached significance within the 9p22.2 region, but only one, rs381413, retained significance after multivariate regression analysis (193). In subsequent studies, candidate loci nearby on 9p13, rs8170 and rs236356 met significance, which are within the MERIT40 gene that interacts with BRCA1, and therefore functional plausibility (194). Nine additional SNPs with  $p$  values  $<10^{-4}$  and two approaching genome-wide significance on 2q31 and 8q24 have been identified in the consortium cohort, all in serous histology subtypes. There is support of functional role in a number of genes in these regions, including HOXD1, MYC, TIPARP, SKAP1 and ESR1 on 8q24 and 2q31 and BNC2 on 922 (195,196).

**89.11.1.1 KRAS Variant.** Micro RNA (miRNA) is a class of 22 nucleotide noncoding RNAs that are evolutionarily conserved and negatively regulate gene expression by binding to partially complementary sites in 3'-untranslated regions of target messenger RNA. miRNAs are aberrantly expressed in almost all cancers and function as novel class of tumor suppressors and oncogene regulators (197). SNPs within the miRNA or the miRNA-binding sites can act as biomarkers of cancer risk. The rs61764370 germline KRAS variant disrupts *let-7* binding to KRAS and increases levels and has been shown to be disproportionately present in various cancers including lung, colon and ovarian. A case-control study examined the prevalence of KRAS variant in several 100 unselected ovarian cases and 31 HBOC, BRCA-negative families and found an RR of 1.7 in sporadic cases and an odds ratio (OR) of 2.46 for ovarian cancer among carriers of the variant. This led to a commercial SNP test called "PreOvar™," which is currently available in the United States (198,199). Because this variant did not show significance in GWAS, an analysis was performed on 8669 ovarian cases and controls from 19 case-control sets and powered to detect an RR over 1.3 for sporadic cases and 2.0 for familial cases. This provides substantial argument that there is no evidence for association between rs61764370 and epithelial ovarian cancer in univariate analysis (200), though the investigators of the initial study dispute this and the test remains available.

## 89.12 CERVICAL CANCER

The major etiologic factor in both squamous and adenocarcinoma of the cervix is undoubtedly human papillomavirus (HPV), particularly types 16, 18, 31 and 33

(201,202). Predisposition to the effects of the virus can be associated with overt immunologic deficiencies (203), which may be genetic or acquired (e.g. renal transplant recipients). There is also some evidence of interaction between specific papillomavirus types and certain histocompatibility antigens, suggesting a possible genetic basis for susceptibility to cervical cancer (204). For example, the HLA-B7 allele presents an immunogenic octapeptide epitope of HPV type 16 that shows frequent variation to a nonimmunogenic form. The latter variant has been found most commonly in tumors from HLA-B7-positive women and may contribute to the adverse prognosis of cervical cancer associated with the B7 allele (205).

Although initial surveys of cancers arising in BRCA1 mutation-bearing families did not detect a significant excess of cervical tumors, the Breast Cancer Linkage Consortium reported an increase in risk (16), but this has not been reported subsequently.

There is a suggestion of an excess of cervical tumors among families with LFS (206,207), but this does not appear to be a consistent finding and certainly does not constitute a measurable familial component in the incidence of cervical cancer. Several SNPs have been associated with cervical cancer but none meaningfully validated or reproduced to date. In a small Monte Carlo model study, candidate genes with a multilocus approach showed an epistatic effect between CD28 and IFNG among a comparison of SNPs in 12 genes (208). As mentioned above in the discussion of TP53 mutations, because of the suggestion of increased risk for cervical cancer among women with LFS, Hu et al. investigated functional polymorphisms in 577 family trios and noted a TP53Arg variant associated with susceptibility to cervical cancer, particularly in those infected with HPV type 16 (209).

In the rare inherited dyskeratosis syndrome, squamous carcinoma of the cervix, vagina, or vulva can occur, but such conditions are believed to make only a minuscule contribution to the overall frequency of these tumors (210).

## 89.13 IMPLICATIONS OF FAMILIAL BREAST AND OVARIAN CANCERS FOR CLINICAL PRACTICE

From having been a neglected area, within the past 15 years, the issue of hereditary predisposition to common cancers has come to occupy a prominent place in the public eye. It is widely discussed in the popular media, and growing numbers of women who are concerned about their family histories of breast or ovarian cancer are seeking medical help (211). Many "cancer family" clinics have been established in response to this demand (212,213). Penetrance estimates vary widely and by study design and population investigated. Table 89-6 provides penetrance estimates for breast and ovarian cancers, by decade of age until age 70, based on a meta-analysis of the 10 most robust studies over the past 15 years.

**TABLE 89-6 Meta-analysis of Cumulative Risk for Breast and Ovarian Cancers by Decade of Age**

(A)										
Current Age (years)	Risk (%) of Developing <i>Breast Cancer</i> by Decade of Age									
	30 Years		40 Years		50 Years		60 Years		70 Years	
	BRCA1	BRCA2	BRCA1	BRCA2	BRCA1	BRCA2	BRCA1	BRCA2	BRCA1	BRCA2
20	1.8	1	12	7.5	29	21	44	35	54	45
30			10	6.6	28	20	44	35	54	45
40					20	15	38	30	49	42
50							22	18	37	32
60									19	17

(B)										
If You Are (in years):	Risk (%) of Developing <i>Ovarian Cancer</i> by Decade of Age									
	30 Years		40 Years		50 Years		60 Years		70 Years	
	BRCA1	BRCA2	BRCA1	BRCA2	BRCA1	BRCA2	BRCA1	BRCA2	BRCA1	BRCA2
20	1	0.19	3.2	0.7	9.5	2.6	23	7.5	39	16
30			2.2	0.52	8.7	2.4	22	7.4	39	16
40					6.7	1.9	20	7	38	16
50							15	5.2	34	14
60									22	9.8

Risk for breast (A) and ovarian (B) cancers for an unaffected woman carrying a BRCA1 or BRCA2 mutation beginning at age 30 until age 70. Ten studies included in this meta-analysis by Chen and Parmigiani include the original Breast Cancer Linkage Consortium risk figures and other studies that predict risk until age 80, but tables are truncated at age 70. Chen, S.; Parmigiani, G. Meta-analysis of BRCA1 and BRCA2 Penetrance. *J. Clin. Oncol.*, 2007, 25(11), 1329–1333. (From Morris, J. L.; Gordon, O. K. *Positive Results: Making the Best Decisions when You're at High Risk for Breast or Ovarian Cancer*; Prometheus Books, Amherst, NY, 2010. Reprinted with permission of Prometheus Books; [www.prometheusbooks.com](http://www.prometheusbooks.com).)

### 89.13.1 Management Options

**89.13.1.1 Enhanced Surveillance.** The US NCCN and the UK NICE guidelines on the surveillance for BRCA1/2-related hereditary breast–ovary syndrome are for the semiannual imaging of the breast with magnetic resonance imaging (MRI) and mammogram—alternating each on an annual basis beginning at age 25, clinical breast examination twice yearly and twice yearly transvaginal ultrasound (TVU) and CA-125 levels ([www.nccn.org](http://www.nccn.org)) (214). Surveillance for ovarian cancer is considered as an intermediary until definitive prophylactic preventive surgery is undertaken, given the limitations to screening efficacy for ovarian/tubal/peritoneal cancer.

Evidence is now clear that annual screening is of less benefit to carriers of BRCA1 mutations than to women with a family history of breast cancer but without demonstrable mutations. The former are more likely to have high-grade tumors that carry a substantial risk of progression even if detected while small and node-negative (215,216). This is entirely in keeping with the finding that non-BRCA1 and non-BRCA2 familial breast cancers tend to have good prognostic features (53). As mentioned previously, the issue of radiation risk from mammography is currently unresolved and may be a significant factor if some of the cancer-predisposing mutations increase sensitivity to ionizing radiation. p53 is a case in point, as radiation-damaged cells in the absence of functioning p53 fail to arrest cycling during the repair phase or to undergo apoptosis when the damage is irrecoverable (217). Nevertheless, there is no direct evidence that the doses of radiation

associated with mammography (even repeated at regular intervals) have any measurable clinical consequence, but because of recent mathematical modeling study that very early initiation of mammography (at younger than 30 years) among BRCA carriers may be associated with excess cancers, guidelines are currently cautious regarding mammography at younger than 30 years in BRCA carriers (218). MRI of the breast is the mainstay of surveillance for high-risk women, with initial studies of BRCA carriers comparing mammogram, ultrasound, and MRI demonstrating much higher sensitivity for detection of invasive cancer (219). Subsequent studies confirm that MRI (with gadolinium contrast enhancement) outperforms mammography in the detection of very small, noncalcified lesions, but it is less well suited to recognition of ductal carcinoma in situ (DCIS) (220). Therefore, MRI may be of particular value for surveillance of women with BRCA1 mutations, in whom DCIS is often absent. NCCN and American Cancer Society surveillance recommendations now consider it standard of care for BRCA carriers to have annual mammogram and annual MRI (alternating every 6 months) after the age of 25 years (221). Not all women can tolerate the close confinement of the MRI scanner, and the examination is likely to remain very expensive. In 2009, the American College of Radiology modified guidelines for MRI to include any woman with an empiric lifetime risk of greater than 20% or who have extremely dense breast tissue via mammography. This initiated a deluge of screening breast MRI for a very heterogeneous group of women—it remains to be seen what is the optimal group of patient characteristics suited for various

imaging modalities. Among general practitioners, however, despite widely available standard of care recommendations for screening of BRCA and other hereditary carriers, actual practice ranges very broadly (222).

For women at increased risk for ovarian cancer, early detection (or, better still, prevention) is of paramount importance because prognosis is very closely related to stage at diagnosis. In most centers, the mainstay of ovarian cancer screening is regular (semiannual) ultrasound examination with a transabdominal or transvaginal probe in combination with CA-125 levels.

Glycoprotein markers in the plasma, such as CA-125, and, more recently, HE-4 are of great value in following the course of disease and the patient's response to chemotherapy in women affected with ovarian cancer. However, as a screen, CA-125 and every other serum marker evaluated to date have been inadequate. A single CA-125 test alone is not effective at detecting ovarian cancer, but serial testing and the use of receiver operating characteristic (ROC) curves have been much more promising (223). Furthermore, because normal levels fluctuate with the menstrual cycle, and other diseases can cause CA-125 levels to rise, including endometriosis, benign ovarian cysts, early-stage pregnancy, and pelvic inflammatory disease, the false-positive rate in premenopausal women is 3%, which can be a source of alarm. Multi-center trials are ongoing in assessing the combination of CA-125 and HE-4 as a stand-alone screening assay for BRCA carriers, HNPCC carriers, and women with significant family history ([NCTrials.gov](http://NCTrials.gov)) (224).

The US National Cancer Institute has begun a long-term trial on the effectiveness of TVU and the CA-125 test, alone and in combination, for detecting ovarian cancer in high-risk women (225). A large population screening UK study investigated the use of ultrasound, alone and in combination with CA-125, for detecting ovarian cancer in postmenopausal women of average risk for ovarian cancer (226). Though 50% of cancers detected were of early stage, the remainders were still stage III and stage IV and continued to have high false-positive rates, commiserate with prior studies.

Despite careful application of the best available technology, however, there is as yet no direct evidence that screening programs for hereditary ovarian cancer are having any impact on morbidity or mortality. The alternative of prophylactic bilateral salpingo-oophorectomy, at around age 40 for BRCA1 carriers, and closer to menopause for BRCA2 carriers and for women at substantial familial risk for ovarian cancer, appears to be a much better option (227,228). Nevertheless, prophylactic oophorectomy is not a risk-free procedure (229) and can be associated with some negative psychological effects, including loss of libido. There has been concern about the long-term consequence of premature menopause in women who undergo risk-reducing oophorectomy, but the results of PROSE (Prevention and Observation of Surgical Endpoints) trial demonstrate a reduction in

all-cause mortality for women with BRCA1 and BRCA2 mutations who undergo oophorectomy (230).

**89.13.1.2 Preventive Medication.** Not only is the risk for a first breast cancer markedly elevated but also the risk for a second primary cancer in the contralateral breast after an initial unilateral cancer diagnosis in a BRCA mutation carrier is up to 29.5% at 10 years (231). There is good evidence that the nonsteroidal antiestrogen tamoxifen, given from 2 to 5 years to women who have had a stage I breast cancer, reduces the risk for a second primary breast cancer by approximately 35% (232). This is in keeping with a huge body of evidence implicating estrogen in the etiology of breast cancer. However, the question of whether tamoxifen may be protective in women at genetically increased risk for breast cancer is not a simple one (233,234). Not only is there concern about the possible induction of endometrial cancer but there is also debate about the duration of any protective effect because resistance to tamoxifen tends to develop within a few years in established cancers (235). The same time course may not apply when the drug is used prophylactically, but if intervention has to begin by about age 30, it may be unrealistic to expect benefit to be sustained for decades, even though it has been shown to persist for 10 years in the early cancer trials cited earlier. Pure antiestrogens are improved alternatives to tamoxifen as adjuvant therapy for breast cancer, and cross-resistance has not been reported. However, they lack the advantages of tamoxifen, for example, in protection against osteoporosis, and actually accelerate bone loss (236,237).

The US National Surgical Adjuvant Breast and Bowel Project double-blind P-1 trial of prophylactic tamoxifen showed a highly significant reduction in risk for invasive breast cancer in those on the active drug (179). Initial results from the United Kingdom (International Breast Cancer Intervention Study) and the Italian trials were less encouraging (238). However, with longer follow-up, all trials combined showed a significant protective effect of tamoxifen or raloxifene (almost 40% reduction in breast cancer incidence, compared with placebo). This reduction applied only to ER-positive tumors but was not restricted to any particular age group (178,239). Aromatase inhibitors demonstrate improved efficacy over tamoxifen adjuvant treatment of breast cancer and a primary prevention trial in women defined as high risk based on age, Gail risk greater than 1.66% over 5 years, or personal history of atypical hyperplasia or DCIS, but specifically excluding BRCA carriers. Results of the exemestane (aromatase inhibitor) MAP.3 trial in postmenopausal women at empiric risk for breast cancer above the 1.6% year risk demonstrated substantial efficacy, but BRCA carriers were specifically excluded from this study (240).

The use of the combined oral contraceptive pill and hormone replacement therapy is often raised as an issue of concern in the family cancer clinic. Most of the data on the oral contraceptive pill (234,241) relate to

preparations no longer in use, which contained higher doses of estrogen than does the modern pill. Regardless, there is overwhelming evidence that the use of combined oral contraceptives reduces the risk for ovarian cancer among carriers of BRCA1 and BRCA2 mutations by as much as 50% (191). This may well be at the expense of some small increase in risk for breast cancer (242,243).

Hormone replacement therapy can be dramatically beneficial for some women suffering from severe menopausal symptoms. Particularly when prophylactic oophorectomy has been carried out (see later), estrogen replacement, in a dose just sufficient to relieve symptoms and for as short a period as seems clinically appropriate, is justified and is unlikely to add measurably to the cancer risk (243). Long-term therapy, especially with combined estrogen and progesterone, is probably contraindicated in those who do not undergo preventive surgery (17,234,244).

**89.13.1.3 Risk-Reduction Surgery.** Without dispute, the most effective cancer prevention strategy for individuals at high risk is with prophylactic surgery. Prophylactic mastectomy reduces breast cancer risk in BRCA mutation carriers by at least 95% and has been reported to reduce risk to less than 1% in one recent study of unaffected women (245). In addition, although the impact of a prophylactic contralateral mastectomy on survival may depend on the overall survival from the initial ipsilateral breast cancer, in women already affected with cancer, contralateral mastectomy has been shown to reduce contralateral breast cancer incidence by up to 97% among BRCA mutation carriers (246), therefore having an effect on morbidity. Prophylactic salpingo-oophorectomy reduces the risk for ovarian/fallopian tube/peritoneal cancer by 80–90+ percent in BRCA mutation carriers and has been associated with significant reductions in both breast cancer- and gynecologic cancer-specific mortality among this group.

Large published series of total prophylactic mastectomy for familial risk record reductions in cancer risk of more than 90%, with follow-up periods in excess of 10 years (83,247), even though in this original data, a variety of surgical techniques were utilized and women were characterized as high risk by family history or LCIS (lobular carcinoma *in situ*) and not by BRCA status. As in the case of prophylactic oophorectomy, unsuspected tumors are sometimes found in breasts removed prophylactically from women at high genetic risk (248).

The question of total bilateral mastectomy often arises at the time of first breast cancer diagnosis in a known BRCA1 or BRCA2 mutation carrier, or when there is a strong family history, even in the absence of molecular confirmation. Certainly, the long-term risk for contralateral breast cancer after conventional management of the first tumor is high—from 3–6% per year (36,40). Additionally, although the outcome of conservative (breast-conserving) management of the presenting tumor is generally satisfactory, and the incidence of

a second primary breast cancer appears to be very low in the first two after cytotoxic chemotherapy for a first cancer, the required radiation therapy can significantly impair future reconstructive options and there is controversy over whether there is an increased incidence of ipsilateral second primary cancers in BRCA carriers who have had breast conservation and radiation therapy (249,250–252).

Historically, prophylactic mastectomy was viewed with considerable unease in most cultures (253), though when undertaken, the procedure is usually very successful in improving the quality of life (254). Variations in the uptake rate of prophylactic surgeries are thought to be influenced by a number of factors, including differences in healthcare costs and access to care and differences in providers' recommendations. Interestingly, Metcalfe and colleagues found lower rates of uptake of prophylactic surgeries among women who had access to a universal healthcare system (in which preventive surgery and reconstruction are available at no cost) than among women from the United States, most of whom rely on private health insurance (231).

Of the 1383 women without breast cancer from nine different countries, only 248 (18%) had undergone prophylactic mastectomy at a mean of 3.9 years after genetic testing, while 52.1% of all women in their study had prophylactic salpingo-oophorectomy. The authors noted large differences in the uptake of preventive surgeries by country. The United States had the highest uptake of prophylactic mastectomy at 36.3%, compared to Canada (22.4%), Poland (2.7%), and Israel (4.2%). A similar trend was noted for the uptake of prophylactic salpingo-oophorectomy, with the United States having the highest rate of uptake at 71.1%.

In another study, Metcalfe and colleagues demonstrated that family history is a strong predictor of the uptake of cancer-preventive procedures among women with BRCA mutations (245,255). In their study of 517 BRCA mutation carriers, they found that women with a mother with breast cancer trended toward having a higher uptake of prophylactic mastectomy than those without, although the result was not statistically significant ( $p = 0.01$ , OR = 1.7). In addition, they found that women with a sister with breast cancer were more than twice as likely to have a prophylactic mastectomy than those without ( $p = 0.003$ , OR = 2.4), and women with a mother or sister with ovarian cancer were more likely to have prophylactic salpingo-oophorectomy than those without ( $p = 0.04$ , OR = 1.6) (245,255).

Early published "Decision Analyses" attempting to predict the effects of screening and intervention in familial breast and ovarian cancers had been based on unproven assumptions about the relative efficacies of the different options available and have not always allowed for differences in outcome between carriers of BRCA1 or BRCA2 mutations, or none (256,257). A more recent study of this type, which utilizes a Monte Carlo survival analysis

that takes greater account of accrued clinical evidence, suggests that prophylactic surgery offers appreciable survival advantages over surveillance for young mutation carriers, with maximum benefit to BRCA1 carriers if prophylactic mastectomy and salpingo-oophorectomy are complete by age 40 and with little additional benefit for very young prophylactic mastectomy (age 25 versus 40) (228,258). The combination of prophylactic mastectomy and prophylactic salpingo-oophorectomy at age 40 improves survival more than either intervention alone, with a 24% survival gain for BRCA1 mutation carriers and an 11% gain for BRCA2 mutation carriers (258).

Oophorectomy not only provides substantial protection against ovarian cancer but also reduces the risk for breast cancer by almost 50% over the succeeding 5 years if completed by age 40. The level of protection was even greater on longer follow-up and was not reversed by the use of hormone replacement therapy (17,259–261). The explanation for this protective effect of oophorectomy is uncertain, given that a high proportion of BRCA1 breast cancers are ER-negative, but the findings are very clear and are in keeping with the protective benefit seen by the use of tamoxifen as well. There is speculation that all breast cancers may initially be estrogen-responsive, such that the reduction in hormonal stimulation to the breast from oophorectomy and selective ER modulators like tamoxifen have a chemostatic effect on breast proliferation (262). Primary peritoneal cancer, histologically indistinguishable from serous ovarian cancer, has been recorded in a substantial number of patients following prophylactic oophorectomy, which therefore does not confer total protection (184). There is continuing debate over the origin of such tumors, seedlings from microscopic ovarian cancers undetected at prophylactic oophorectomy or a “field change” in the peritoneal epithelium, which is embryologically identical to the outer layer of ovarian cells. The fact that in some instances a primary peritoneal tumor has presented 10 years after oophorectomy perhaps favors the latter explanation, as does the evidence from X-inactivation analysis, that such tumors are often multifocal (263). The incidence of this outcome is uncertain. A figure of 2.8% is quoted by Piver and colleagues (184). A series of studies (17,259,264) suggested that the risk is 1–2%, with a follow-up period of 2–8 years from the date of oophorectomy, but in a more recent meta-analysis by Rebbeck, the risk reduction for ovarian cancer was only 80%. One of the largest studies in the analysis though included patients who had only been treated with oophorectomy and not salpingo-oophorectomy, which was the routine practice for risk reduction before 2000, when the risk for fallopian tube cancer became clear (265). In the larger of these series, unexpected ovarian cancer was diagnosed in several patients at the time of “prophylactic” surgery, and this experience has been replicated in many other centers, and risk for incidental malignancy detected at time of prophylactic surgery is quoted to be between

3 and 6% (264–266). Hence, prophylactic oophorectomy is now referred to as risk-reduction bilateral salpingo-oophorectomy. The American Society of Clinical Oncology and Gynecology Oncology Group recommend preventive surgery be completed as a staging procedure with peritoneal biopsy and pelvic washings, usually by or accompanied by a gynecologic oncologist. Tubal ligation, without oophorectomy, has been found to reduce the subsequent risk for ovarian cancer among BRCA1 (but not among BRCA2) mutation carriers, although the mechanism of this effect is unclear (267).

## 89.14 IMPACT OF DEFINITIVE GENETIC DIAGNOSIS ON CLINICAL PRACTICE

### 89.14.1 Clinical Considerations

BRCA testing has exploded over the past few years due to improved reimbursement by insurance companies, more liberal testing criteria, and increased awareness among the clinicians and the general public. Myriad Genetics Laboratory, holders of the BRCA1/2 patent in North America and the United Kingdom, reports the number of BRCA tests increasing from 50,000 to more than 500,000 over the past decade (Myriad Laboratory, personal communication). Because of that, BRCA is often thought to be synonymous with hereditary breast cancer. However, more than half of pedigrees consistent with hereditary breast cancer will test negative for a BRCA mutation. Intense investigations over the past decade have failed to uncover a “BRCA3” that has implications for more than just a few isolated families. As reviewed previously, PALB2 and CHEK2 can present as hereditary breast cancer with fairly penetrant pedigrees but probably do not account for more than a few percent of BRCA-negative families. Because *de novo* TP53 changes can be responsible for breast cancers in young women, TP53 gene testing should always be considered in a woman with very early-onset breast cancer who tests negative for a BRCA mutation (Table 89-3).

Integration of genetic testing in the initial treatment plan of the patient is also increasing for hereditary breast and gynecologic cancers. Point-of-care testing at the time of breast cancer diagnosis is becoming much more common, so that women can make definitive surgical decisions and avoid the radiation therapy or the need for suboptimal reconstruction at a later time.

### 89.14.2 Prospects for Targeted Treatment and Preventive Therapy

An understanding of the biologic functions of these genes, and how these functions are disrupted by mutation, will be the key to the development of specific corrective or compensatory strategies, based on new pharmacologic agents. Careful evaluation for underlying genetic susceptibility as well as particular histologic profiles of cancer

becomes an increasingly important task as we move swiftly into the era of molecular diagnosis.

The very apparent differences in survival in ovarian cancer patients with BRCA mutations were postulated to be due to differential response to chemotherapeutic agents. Because most chemotherapeutic agents work by directly or indirectly damaging DNA, the role of BRCA mutations has been of interest for several years in targeting therapy (268) (in vitro assays of cultured breast cancer cells demonstrated substantial differential sensitivity to taxanes, a standard chemotherapeutic agent in the adjuvant treatment of breast cancer). BRCA null cells were 1000 times more resistant to taxanes and extremely sensitive to alkylating agents such as platinum drugs (269). Although this has led to generalized support for BRCA status to be used as a stratifier for treatment (264), this has not translated into clinical treatment changes until recently, where trials have begun comparing platinum drugs with poly(ADP-ribose) polymerase 1 (PARP1) inhibitors for ovarian cancer as well as *cis*-platinum in BRCA-related breast cancers as well as triple-negative sporadic breast cancer (42A).

**89.14.2.1. PARP1 Inhibitor.** The concept of synthetic lethality was described 50 years ago and is when two mutations are benign individually but result in cell death when combined (270). To repair both endogenous and exogenous DNA damage, cells utilize a range of DNA repair mechanisms. They are largely divided into single-strand break (SSB) and double-strand break repair mechanisms. The SSB mechanics include base excision repair, nucleotide excision repair and MMR. HR and nonhomologous end joining are DNA double-strand repair mechanisms. When the DNA repair pathway is compromised as with BRCA1/2 deficiency, this feature may be exploited as a cancer therapeutic with a PARP inhibitor (269).

When DNA SSBs encounter DNA replication forks, they can cause the fork to stall or collapse, which then creates subsequent double-strand breaks. Normally, these double-strand breaks are repaired quickly by the HR pathway. The hypothesis for the drug target known as a PARP1 inhibitor proposed that BRCA null (–/–) tumor cells have defective HR pathway. When tumors are treated with a PARP inhibitor, the cells must rely on alternative, less precise mechanisms to repair the breaks, which result in genomic instability and cell cycle arrest (271). In two recent phase II multicenter studies of the effectiveness of olaparib, an orally active PARP inhibitor, patients were randomized to one of two doses of olaparib, after having been on at least three different prior chemotherapies. Subjects had to have measurable disease and had been treated with at least three different chemotherapies. In the higher dose, the arm given 400 mg had a 41% objective response rate with minimal toxicity (272,273). Phase III trials are underway using PARP1 inhibitors alone in less heavily treated patients and in combination with single agents.

Developing assays to delineate molecular biomarkers of response to PARP inhibitors in “sporadic” tumors with acquired defects in the HR system is critically important as there are a large number of patients with breast cancers who show a high degree of “BRCAness” but for whom no germline mutations are detected.

This is the entry into an exciting era into personalized therapy where cancers are treated on the basis of their underlying molecular characteristics and no longer as one disease. Ultimately, this may translate into preventive therapy as well, but this is a far more challenging prospect because of the heterogeneous nature of risk, and more importantly the unknown long-term consequences of a DNA damage repair mechanism being “inhibited” in all tissues.

### Biography

Ora Karp Gordon, MD, MS, is director of the GenRISK Adult Genetics Program, and director of Genetics for the Wasserman Breast Cancer Prevention Program at Cedars-Sinai Medical Center, as well as medical genetics director for the Disney Cancer Center at Providence St Joseph Hospital. She is an associate professor of medicine at the University of California, Los Angeles, David Geffen School of Medicine.

A diplomat of the American Board of Internal Medicine and the American Board of Medical Genetics, Dr Gordon's primary research interests involve the prevention of breast cancer. She is involved in numerous clinical trials for cancer prevention and genetic disorders of connective tissue. She coauthored an award-winning consumer healthcare book on understanding and managing breast and ovarian cancer risk.

## Disorders of the Body Mass

*Patricia A Donohoue and Omar Ali*

Medical College of Wisconsin, Milwaukee, WI, USA

### 90.1 OVERVIEW

There are numerous human conditions that produce both elevated and reduced body mass, and extremes at both ends of the body-size spectrum are associated with increased relative risk of mortality (1). This chapter will be devoted to increased body mass associated with excess fat stores (obesity). Obesity-associated comorbidities include significantly increased risks for diabetes, cardiovascular disease, the “metabolic syndrome,” cancer (2), respiratory disease (asthma, sleep apnea), infertility, degenerative joint disease, depression, anxiety, and discrimination both in social life and in the workplace. It is likely that diabetes-related morbidities will contribute most to the disabilities related to obesity (3). The *metabolic syndrome*, defined as the combined presence of obesity, hyperinsulinemia, hypertension, and hyperlipidemia, is increasing in prevalence in parallel with obesity in adults (4) and in youth (5,6). For the first time in known history, the life expectancy in the United States may potentially decline because of, in large part, the obesity epidemic (7). The etiology of human obesity is undoubtedly multifactorial, reflecting complex interactions between genetic background, environmental conditions, and developmental processes.

#### 90.1.1 Definition

Centers for Disease Control and Prevention (CDC) defines individuals as obese whose body mass index (BMI) (weight in kilograms divided by the square of the height in meters;  $\text{kg}/\text{m}^2$ ) exceeds the age- and sex-specific 95th percentile. Those who have a BMI between the 85th and 95th percentiles are overweight and are at increased risk for obesity-related comorbidities. High BMI correlates well with excess body fat in all age groups and in both genders, with the exception of persons with very high muscle mass (e.g. “body builders”). A cutoff of

$>30 \text{ kg}/\text{m}^2$  is accepted as defining obesity in adult Americans. For growing children, age- and sex-specific BMI standards are used (Figure 90-1).

In the past, the CDC recommended that the term obesity be avoided, and that the following terms be used: At risk for overweight—BMI between the 85th and 95th percentile for age and gender; overweight—BMI higher than 95th percentile for age and sex. But in 2010, based on the recommendations of an AMA expert panel, it was decided that the terminology for children would be the same as that used in adults, i.e. children whose BMI ranges from the 85th to 95th percentile for age and sex would be classified as overweight and those who exceed the 95th percentile will be classified as obese (8).

The regulation of body fat stores is complex, and is controlled by the interaction of environment and genetic background. The great importance of environmental factors on body size is underscored by the marked increase in obesity prevalence over the past 30 years, a time period whose brevity most certainly did not allow for a significant change in the gene pool. The prevalence of obesity is increasing at a dramatic rate. This is illustrated in a dramatic animation of US obesity prevalence by states compiled by the CDC (<http://www.cdc.gov/obesity/data/trends.html>). The prevalence is significantly higher, and the trend is even more pronounced, in American minority groups, particularly in females. This is not only occurring in adults (9) (Figure 90-2), but in youth as well (5) (Table 90-1). There is some indication that the trend may be flattening in some groups, but in others, the prevalence of overweight and obesity continues to rise. This pattern has been observed throughout the United States (10–12), has accelerated over the past 15 years, and is mirrored by a rise in the prevalence of type 2 diabetes mellitus in adults and youth. International trends parallel those of the United States (13,14). The prevalence in a given population, such as China, must be determined

using population-specific standards in order to avoid underestimating the scale of the problem (15).

The impact of environment on the epidemic of obesity includes unfavorable trends in food intake and physical activity, as well as barriers to reversing these trends (16). The impact of environment on body size is also underscored by the development of obesity in patients who have survived leukemia (17,18), or who have suffered hypothalamic damage (19), especially patients treated for craniopharyngioma (20). In addition, a human virus has been implicated in the etiology of animal obesity (21,22) and human obesity (23).

While this pronounced secular trend is almost certainly environmental, it is also clear that there is a significant heritable component in obesity risk, and that this genetic component explains up to 80% of the variation in BMI within a given environment. This genetic risk of obesity may have been acquired during the stage of human evolution when acquisition of food was achieved through strenuous activity (hunting, digging, etc.), and periods of prolonged fasting and famine were constant threats, that genotypes were enriched to favor energy storage. In the current environment of plentiful and easily accessible high-calorie food, these so-called “thrifty

genotypes” are highly prevalent and, unfortunately, are now detrimental. This evolutionary pressure to prevent weight loss has led to the “absence of protection” (against weight gain) model of genetic control of obesity. Another model, termed the “Central Resistance” model, suggests that human genetic background would provide equal defenses against weight gain or loss, but that additional genetic or acquired defects impair the homeostatic control (24). In addition to absolute difference in BMI, body composition and the distribution of body fat also play an important role in the development of obesity-related morbidities (25) and variation in body

fat distribution also includes a genetic component (26). Body fat may be preferentially located in the abdomen (android or central obesity pattern) or surrounding the hips and thighs (gynoid obesity pattern). The android obesity pattern is more strongly associated with dyslipidemia, hypertension, and glucose intolerance (27), and is associated with increased intra-abdominal or visceral fat stores. This is the complex of features known as the *metabolic syndrome*. Thus, even at the same level of overweight, an individual with a greater amount of visceral fat is more likely to have or develop serious health consequences associated with obesity.

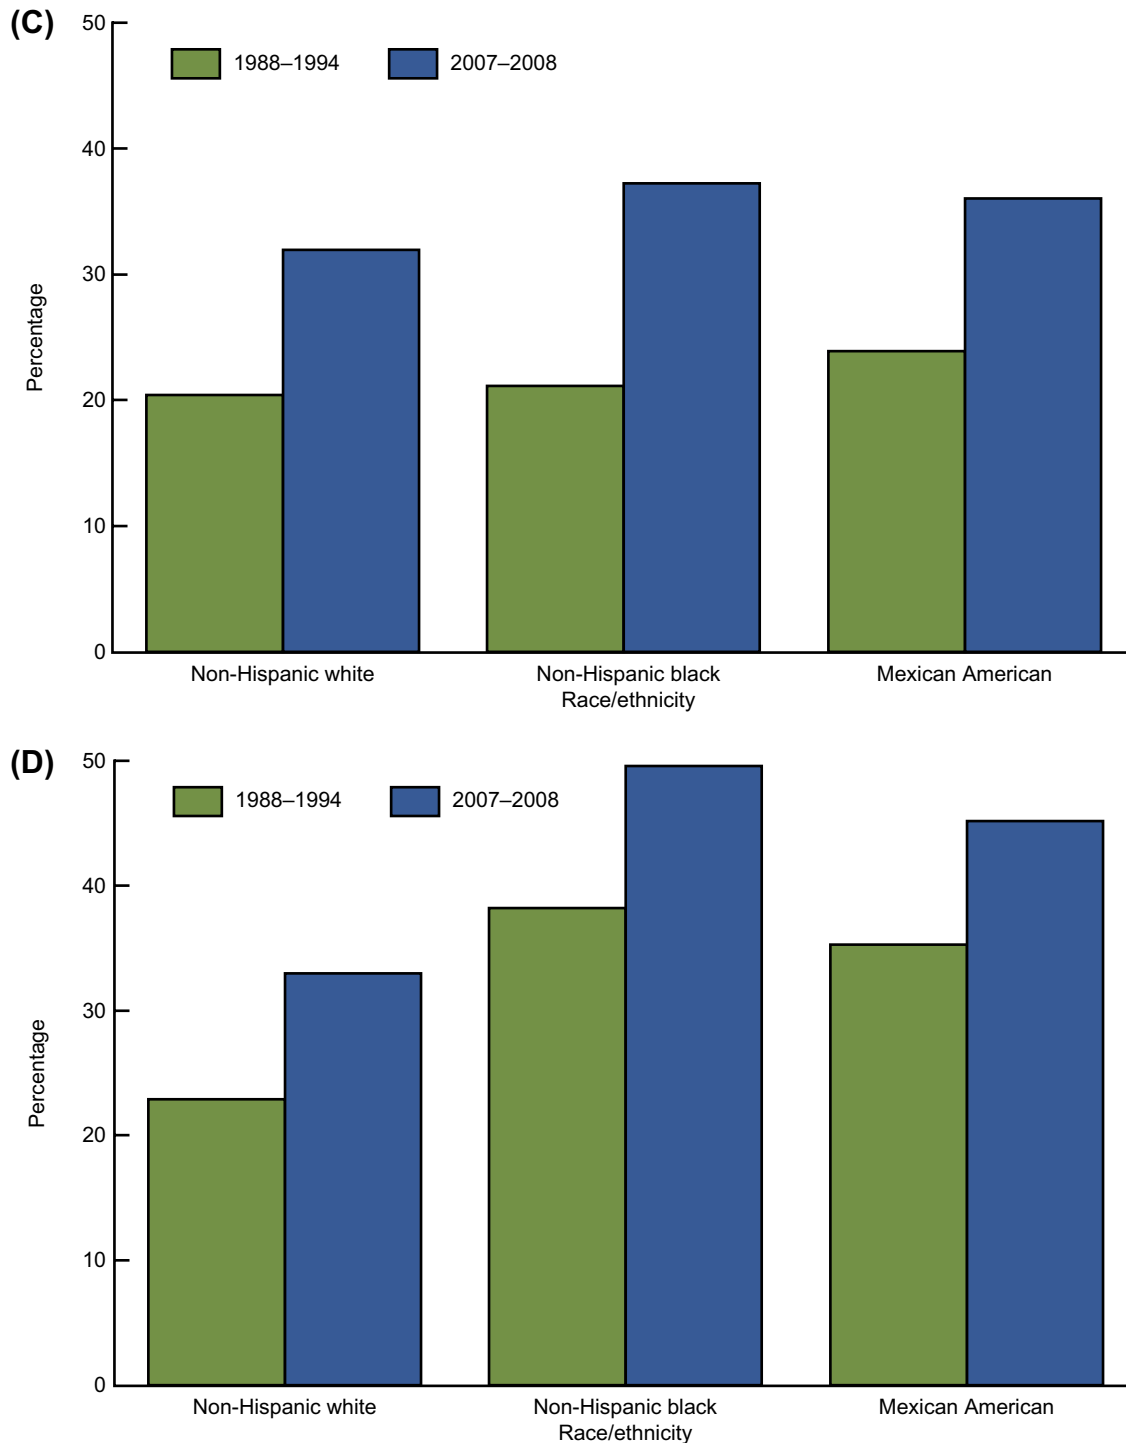

**FIGURE 90-2** A. Trends in overweight, obesity, and extreme obesity among adults aged 20 years and over: United States, 1988–2008. B. Trends in overweight, obesity, and extreme obesity among adults aged 20–74 years: United States, 1960–2008.

### 90.1.2 Heritability of BMI

The important influence of heredity on human body size has been demonstrated in multiple studies of dizygotic and monozygotic twins, and of adopted individuals and their biological siblings (28). Studies of twin pairs have consistently demonstrated higher concordance for body size among monozygotic than dizygotic twins. In a study of 1974 monozygotic and 2097 dizygotic pairs, concordance for body size at six different degrees of overweight (15, 20, 25, 30, 35, and 40% overweight) at approximately 20 years of age were 1.9–3.6-fold higher for monozygotic than dizygotic pairs (29). In a study of adult adoptees and their biological siblings, both full and half sibs, there was

a significant correlation of BMI in biological sibs across the entire distribution of body sizes. This correlation was much stronger for the full sibs (30). In a study of pediatric twins, there was a genetic contribution to percentage body fat (PBF) measured by bioelectric impedance that was distinct from the genetic contribution to BMI. This contribution accounted for 75–80% of the variation in PBF, and 62.5% of the total genetic variation in PBF was due to genes that influenced PBF but not BMI (31).

In *phenotypic* analyses of large unrelated populations, there is statistical evidence for recessive gene effects on body size variables, though the specific genes were not identified. Some examples include BMI in Muscatine,

**FIGURE 90-2** cont'd. C. Prevalence of obesity among men aged 20 years and older, by race and ethnicity: United States, 1988–1994 and 2007–2008. D. Prevalence of obesity among women aged 20 years and over, by race/ethnicity: United States, 1988–1994 and 2007–2008. All figures available in Reference (9).

Iowa (32), BMI in Caucasian and African-American families (33), abdominal visceral fat in Québec (34), relative fat pattern in Utah pedigrees (35), and obesity in American Pima Indians (36).

Studies to identify factors contributing to the genetic epidemiology of childhood obesity have been undertaken using the population of Muscatine, Iowa. This population

has been studied extensively with longitudinal follow-up of body size and relative fatness, cardiovascular risk factors, blood lipid levels, blood pressure, and other phenotypic features for over 40 years. The data obtained from the children in this community established normal ranges for tracking of height, weight, skin fold thickness, blood pressure, cholesterol and triglyceride levels (37).

**TABLE 90-1** Prevalence of Overweight (BMI >95th percentile) for American Children 6–19 years of Age

Years	Age 6–11 years	Age 12–19 years
1963–1970 <sup>a</sup>	4.2	4.6
1971–1974	4.0	6.1
1976–1980	6.5	5.0
1988–1994	11.3	10.5
1999–2000	15.1	14.8
2001–2002	16.3	16.7
2003–2004	18.8	17.4
2005–2006	15.1	17.8
2007–2008	19.6	18.1

<sup>a</sup>1963–1965 data are for 6–11-year-old children, and 1966–1970 data are for 12–17 (not 12–19)-year-old children. Data obtained from References (412) and (5).

The relationship between ponderosity and increased coronary risk factors was established for school children and their family members (38). As an extension of this study, it was demonstrated that there was increased familial cardiovascular mortality among the obese school children (39,40). A longitudinal study of trends in BMI in this population indicated that both genetic and environmental factors were involved in the variability of BMI (32). The data indicated strong support for a single autosomal-recessive locus with a major effect that accounted for almost 35% of the variation in adjusted BMI. Polygenic loci accounted for an additional 42% of the variation. Therefore, only 23% of the variation was not explained by genetic factors and was presumed to represent the environmental influence. The most recent report from the Muscatine Studies show that childhood BMI is the most predictive phenotype for adult obesity (41).

In other communities, longitudinal studies have also demonstrated familial aggregation of obesity and cardiovascular risk. These include the Bogalusa Heart Study (42,43), the San Antonio Family Heart Study (44), the Heritage Study (45), the Québec Family Study (46), and studies of American Pima Indians (47).

Human obesity in rare instances may be associated with defects at a single genetic locus. These include the Prader–Willi (48) and Bardet–Biedl/McKusick–Kaufman Syndromes (49), Alström Syndrome (50), and interstitial deletion of chromosome 18 (q12.2q21.1) (51). The mechanisms by which these genetic defects produce the obesity phenotype are not completely known. Several rare single gene defects produce obesity through better understood mechanisms (see Section 90.3).

An extremely important factor in maintenance of body weight is the relationship between body weight and total energy expenditure (52). The trend toward returning to a specific set point for body weight is powerful, and results from not only a reduction in total energy expenditure in response to weight loss but also an increase in energy expenditure with weight gain. There are no doubt genetic

factors controlling this set point (described in Section 90.2). Sustained weight gain is also associated with an increase in urinary norepinephrine excretion and in serum triiodothyronine concentrations, with the reverse patterns seen with sustained weight loss. The percentage of changes in these parameters correlated with the percentage of changes in energy expenditure (53). Changes in carbohydrate metabolism were also noted. In subjects with sustained weight gain, trends toward insulin resistance were more apparent in those who were obese than in never obese subjects, suggesting to the investigators that there is a threshold effect of total body fat on insulin sensitivity (53). Ethnic variability in resting energy expenditure has been demonstrated, being higher in white than in black prepubertal girls (54), and higher in white than in black prepubertal children, independent of PBF and sex (55). There is ethnic variability in insulin sensitivity and atherogenic risk among adolescents of comparable BMI. Black-obese adolescents have a more diabetogenic insulin secretion and sensitivity profile than white-obese adolescents. On the other hand, the white-obese youth had more visceral adiposity and atherogenic risk factors than their black peers with similar BMI (56). Genetic factors are likely to have major influence on the lower physical activity and resting energy expenditure observed in infants who later become obese children (57). A somewhat genetically isolated population, the Old Order Amish, that is known to have high levels of physical activity has a lower rate of obesity despite high caloric consumption (58).

## 90.2 GENETIC ARCHITECTURE OF OBESITY

The detailed genetic architecture of obesity risk has not yet been precisely defined. Even the true magnitude of the heritability of obesity is not yet settled and estimates range from as low as 20% to as much as 80% (59). A relatively small percentage (5% or less) of obesity cases is due to monogenic or syndromic obesity (60), but most cases are due to complex interaction between multiple genes and environmental factors. Whether the genetic component of this risk is due to multiple common genetic variants of small effect (common disease common variant hypothesis) or whether the effect is due to multiple rare variants or even a few rare variants of large effect has not yet been clarified. But whatever the nature of this genetic influence, it does appear to become more prominent as the prevalence and severity of obesity increases in a given population, indicating that genes influencing obesity may be more aggressively expressed in an obesogenic environment (61).

It is also becoming apparent that individual genomes differ from each other much more than previously assumed; for example, it has been estimated that as compared to the reference haploid genome, each individual human genome on average contains some three and a half million single nucleotide variants (SNV) and about

1000 copy number variants (CNV) of >450 bp, many of which are rare in the population from which the individual was sampled and are unique to the individual's family or clan. Each individual genome is truly unique, not just in terms of sequence variants in individual genes, but in terms of the complex interaction between multiple genes and gene networks. Our models of genetic risk, therefore, need to be modified to take the interplay of multiple variants within each unique individual genome into consideration (62).

In the following pages, we will outline the known monogenic and syndromic forms of obesity, their animal models and human correlates, and the results of recent genome-wide scans and linkage studies of common (polygenic) obesity, keeping in mind that the boundaries between these categories are not sharply defined. Genes and chromosomal regions involved in monogenic forms of obesity are also involved in polygenic common obesity and all forms of obesity are ultimately the product of complex interactions between multiple genes and environmental factors. Thus, the same mutation that causes morbid obesity in one individual may have a significantly attenuated effect in another individual with a different individual genetic background, environmental exposures and family and clan genomic structure.

### 90.2.1 Animal Models and Human Correlates (Spontaneous Mutations)

In rodents, multiple examples of spontaneous single gene mutations producing obesity are known, and form the basis for a candidate gene approach to identify the genes responsible for human obesity (Table 90-2). Several human counterparts of these rodent obesity syndromes have been identified, and will be described in Section 90.3.

**90.2.1.1 Leptin and Its Receptor.** The prototypic obese mice with single gene defects are the obese (*ob/ob*, *Lep<sup>ob</sup>*) and diabetes (*db/db*, *Lepr<sup>db</sup>*) autosomal-recessive mutations. If present on the same genetic background

strain, they cause the identical phenotypes of severe hyperphagia, obesity, diabetes, defective thermogenesis, and infertility due to hypogonadotropic hypogonadism. Parabiosis experiments showed that *ob/ob* animals were unable to produce a circulating factor regulating food consumption, and that *db/db* mice were unable to respond to this factor despite producing it in excessive quantities (63). The phenotype of the *ob/ob* mouse is partially obliterated by adrenalectomy (except for the thermogenic defect) and these adrenalectomized obese mice have significantly increased sensitivity to corticosterone (64). Mice with electrolytic lesioning of the ventromedial hypothalamus (VMH) were found to be resistant to the circulating factor thought to be absent in *ob/ob* mice, but lacked the other phenotypic features of *ob/ob* and *db/db* such as diabetes, defective thermoregulation, and infertility (65). This led to the theory that the VMH was only one of the several sites of action of this circulating "satiety" factor. The phenotypic expression of the *ob/ob* and *db/db* genotypes is highly dependent upon the background strain; for example, the BL/Ks background is associated with more severe diabetes than the BL/6 background (65).

The mutant gene responsible for the phenotype in *Lep<sup>ob</sup>* mice encodes the protein leptin (66,67), which is deficient in these animals. The main site of expression of *ob* (*Lep*) mRNA is white adipose tissue (67). The *Lep* sequence is highly conserved among vertebrates, and the human gene maps to chromosome 7p31. Leptin is a cytokine-like hormone secreted mainly by white (not brown) adipose tissue (67,68), with myriad effects including modulation of satiety and basal energy expenditure, and sexual maturation. Treatment of *ob/ob* mice with recombinant leptin or through leptin gene therapy (69,70) corrects the obesity/diabetes phenotype.

Recombinant leptin treatment causes some weight reduction in normal mice and rats, but has no effect in *db/db* mice (71,72). Recombinant leptin also corrects the infertility in *ob/ob* mice (73), and stimulates early

**TABLE 90-2 Rodent Obesity Mutations, Human Regions of Synteny, and Human Homologs**

Mutation	Gene	Mode of Inheritance (Autosomal)	Rodent Chromosome	Human Syntenic Region	Human Mutation Described	Mutant Protein
Mouse						
Agouti	<i>Ay</i>	Dominant	2	20q11	No <sup>a</sup>	ASP
Diabetes	<i>db</i>	Recessive	4	1p31	Yes	Lepr
Fat	<i>fat</i>	Recessive	8	4q21	No <sup>b</sup>	Carboxypeptidase E
Obese	<i>ob</i>	Recessive	6	7q31	Yes	Leptin
Tubby	<i>tub</i>	Recessive	7	11p15	No <sup>c</sup>	Phosphodiesterase
Rat						
Fatty	<i>fa</i>	Recessive	5	1p31	Yes	Lepr
Corpulent	<i>faK</i>	Recessive	5	1p31	Yes	Lepr

ASP, Agouti signaling protein; Lepr, leptin receptor; CPE, carboxypeptidase E.

<sup>a</sup>ASP prevents binding of  $\alpha$ MSH to its receptor MC4R. Several dominant MC4R mutations are associated with human obesity.

<sup>b</sup>CPE is required for normal prohormone processing by prohormone convertase 1 (PC1). PC1 mutations are associated with human obesity.

<sup>c</sup>Phenotype is similar to human Bardet-Biedl and Usher Syndromes.

reproductive function despite slower growth in normal mice (74). Leptin acts as a “metabolic gate” allowing for pubertal maturation in the rat (75), similar to the effect seen in normal mice. In normal rats, the effects of recombinant leptin are enhanced by VMH injection relative to peripheral infusion (76), and leptin induces rapid modulation of synaptic transmission in isolated arcuate nucleus slices from rat hypothalami (77). In rats with streptozocin-induced diabetes, the iatrogenic leptin deficiency is reversed, and even overcompensated, by leptin treatment. This effect is independent of the amount of weight regained or the resulting blood glucose concentrations (78).

Leptin exists in protein-bound and free states in the plasma, the latter being the predominant form in obese subjects (79). The demonstration of high leptin levels in the plasma of obese individuals correlating with BMI and %BF, along with elevated leptin mRNA in adipose tissue, lead to the hypothesis that obese humans are, to some degree, leptin resistant (80). Leptin levels in plasma are normally higher in women than in men (81–83), and they correlate with %BF rather than genetic background in identical twins discordant for obesity (84). Circulating leptin concentration, when normalized for total fat mass, decreases in males as they progress to late pubertal stages, whereas the reverse trend is seen in females (85). Plasma levels decrease significantly after 60 years of age in both sexes (86). Fasting and sustained weight loss result in a reduction in plasma leptin, however, high-fat diet and energy expenditure *per se* have no effect (83,87). As expected, leptin levels are low in women with anorexia nervosa (88), high in patients with the Prader–Willi Syndrome (PWS) (89), and relatively high in newborns (90), but correlate with %BF in all groups. There is a normal oscillation and diurnal rhythm of leptin levels (91), which shows a blunted pattern in women athletes with amenorrhea relative to athletes with normal menses (92). This perhaps provides a correlation to the defect in sexual maturation seen in *ob/ob* mice. Exposure of cultured human hepatocytes to high concentrations of leptin results in attenuation of insulin-induced activities including downregulation of gluconeogenesis (93), leading to the possibility that leptin is involved in the pathogenesis of the diabetes associated with human obesity.

The gene encoding human leptin has been studied extensively, but with the exception of leptin deficiency caused by rare *LEP* gene mutations (94), its importance in altered human satiety and abnormal body size determination has not been clearly demonstrated. Studies of this gene in large panels of obese and/or diabetic individuals have failed to demonstrate mutations (95–97). Linkage of obesity to this genetic region was not demonstrated in Pima Indians (98), nor in Mexican-Americans with NIDDM (99), and Mexican-American obese sib pairs from Starr County, Texas (100). However, some investigators have shown a suggestion of linkage of polymorphic markers near *LEP* to extreme obesity

(101,102), to obesity-related traits and insulin precursors in Mexican-American families with a type II diabetic proband (103), and to lower leptin levels in obese subjects (104). A leptin gene polymorphism is associated with hypertension, independent of obesity, in a Japanese population (105).

The cloning of the leptin receptor gene *Lepr* (106) from mouse choroid plexus led to characterization of the mutations causing the mouse *db/db* phenotype, and its rat homologs, the Zucker fatty (*fa/fa*) and obese Koletsky phenotypes (107–111). Thus, mutation of the same gene, *Lepr*, occurred spontaneously in three different strains and produced strikingly similar phenotypes. Multiple splice variants of *Lepr* exist (112–114), and are expressed in various tissues within and outside of the central nervous system (CNS), including lung, liver, skeletal muscle and kidney (106), the major site of leptin clearance (115). One of these encodes a circulating (short) form of the leptin receptor, which transports leptin across the blood–brain barrier producing a saturable system of transport into the CNS (79). If excess leptin is secreted, such as in obese individuals with a large fat mass, plasma levels of free leptin will increase significantly because of the saturable transport of the system. The production of this short or soluble form of the receptor is regulated independently by many different physiological conditions, and serves to modulate the amount of free leptin available to the transmembrane signaling long form of the receptor (116).

The cascade of effects downstream of leptin binding to its receptors is not completely understood, but involves activation of members of the STAT family of transcriptional activators (117,118). Both insulin and leptin work in parallel in many of these pathways. Treatment of *fa/fa* (leptin receptor defective) rats with a thermogenic mixture of sympathomimetic amines (ephedrine and methylxanthines) can reverse or prevent their obesity (119,120). Such findings suggest that the downstream effects of leptin include actions on the sympathetic nervous system. This has been confirmed in studies of rodents as well as humans (121,122). Mice that are heterozygous for either the *ob* or the *db* mutation have body composition and leptin homeostasis phenotypes that are intermediate between homozygous wild-type and mutant animals (123).

Other downstream effects of leptin include inhibition of the neurons that produce neuropeptide Y (NPY), a hypothalamic neurotransmitter that can cause obesity through appetite stimulation (described in more detail below), and which is found at high levels in the hypothalami of *ob/ob* mice (124). Leptin also stimulates neurons that increase production of POMC, which is known to inhibit feeding. The NPY and POMC neurons in the arcuate nuclei of mice are rapidly altered by leptin administration. Genetically engineered wild-type and leptin-deficient (*ob/ob*) mice, who express two different green fluorescent proteins in the two neuronal types,

were administered systemic leptin treatment. In the *ob/ob* mice, who normally had increased NPY excitatory synapses and decreased inhibitory POMC synapses, leptin treatment caused a rapid change in this pattern. Within 6 h, before any effect on food intake or weight was observed, the numbers of excitatory and inhibitory synapses became indistinguishable from those of the wild-type, untreated mice (Figure 90-3) (125).

In addition to the effects on feeding, leptin receptor-mediated effects alter bone metabolism, the immune system, angiogenesis, and the cardiovascular system (126,127). Thus, it is clear that animals or humans with defective leptin receptors would require therapeutic intervention aimed at a number of organ systems in order to correct the defect. Multiple factors exist that result in leptin resistance at the tissue level in obese subjects, including interactions with transcription factors that are associated with obesity-induced endoplasmic reticulum (ER) stress. These factors attenuate leptin signaling, and may, in fact, promote more weight gain and adiposity in obese individuals (128).

**FIGURE 90-3** Changes in hypothalamic synapses of *ob/ob* mice after leptin treatment. This diagram demonstrates the difference in the number of excitatory (red) and inhibitory (blue) synaptic inputs onto NPY (coexpressing AgRP) (yellow) and POMC (green) neurons in wild-type and *ob/ob* mice. Leptin treatment to *ob/ob* mice rapidly reversed the number of inputs onto NPY and POMC to wild-type levels. NPY, neuropeptide Y; AgRP, Agouti-related protein; POMC, proopiomelanocortin. Pinto et al. (125), Figure 94-4C, page 114.

In population genetic studies, the *LEPR* region has shown no relation to body size variables in the Pima Indians (98), but a possible correlation was seen with acute insulin response in the same group (129). In the Québec Family Study, results of sib-pair linkage analysis with 137 adult sibships suggested linkage of body fat and insulin levels to polymorphic markers on chromosome 1p32–p22, the cytogenetic location of *LEPR* (130). These markers spanned the regions syntenic with mouse *db* as well as one of the 10 mouse quantitative trait loci (QTLs) related to susceptibility to diet-induced obesity, termed *Do1* (131). Polymorphisms within the *LEPR* introns (130) and exons (132) have been tested for their relationship to obesity in humans. Among these, the sequence variations at coding exons 2 (Lys109Arg), 4 (Lys204Arg and Gln223Arg), and 12 (Lys656Asn) are the most likely to have effects on receptor function. These amino acid substitutions are at positions that are conserved in rat, mouse, and humans. In addition, the codon 223 and 656 variants cause changes in charge (neutral to positive, and positive to neutral, respectively). Of 20 nondiabetic American Pima Indians chosen for extremes in body size, seven *LEPR* sequence variations were identified, including Lys109Arg and Gln223Arg. Three of these variants were within noncoding regions of the gene and these were found exclusively in obese Pima Indians (133). Lys109Arg and Gln223Arg were associated with BMI and fat mass in Caucasians, but not in African-Americans in the HERITAGE Family Study (134). The Lys656Asn variant was significantly linked to BMI in the Muscatine (135), and Gln223Arg was linked to fat mass in the Québec Family Study (136). On the other hand, in adult subjects from Baltimore, Gln223Arg and Lys656Asn were not associated with obesity traits (137), and the codon 109, 204, 223, and 656 changes were not positively associated with juvenile-onset obesity in 56 Danish men (138). However, a meta-analysis of *LEPR* polymorphisms failed to confirm this as an important population-wide locus (139).

Severe early-onset obesity caused by a mutant leptin receptor was originally identified in three female siblings (140). These homozygotes had failure of pubertal development, and reduced growth hormone and thyroid stimulating hormone secretion. Despite absence of leptin signaling, and massively elevated plasma leptin concentrations, leptin mRNA levels in adipose tissue, assessed by quantitative reverse transcription polymerase chain reaction, were as expected for their BMI (141). This argues against a direct negative feedback loop in regulation of leptin gene expression in humans.

**90.2.1.2 Tubby.** The *tubby* (*tub*) mutation in mice is an autosomal-recessive trait, which is associated with less-severe obesity and insulin resistance than *ob* or *db*, is not associated with significant hyperphagia, causes variable degrees of hyperlipidemia depending on background strain, and is more severe in males than females. The phenotype also includes retinal degeneration and sensorineural

hearing loss similar to the human Usher, Alström, and Bardet–Biedl syndromes (BBS) (50,142,143). The mapping (144) and cloning (145,146) of *tub* has led to its characterization as a gene which is expressed mainly in the hypothalamus and encodes a protein with phosphodiesterase-like sequences, possibly affecting cellular apoptosis. Further studies have identified and characterized several Tubby-like proteins (TULPs), mutations of which in mammals can cause retinal degeneration, and/or hearing loss (147), as well as alterations in neural tube formation (148). The exact biological functions of these proteins remain unknown, however, their roles in complex cellular functions are being characterized. They are membrane-bound transcriptional activators that translocate to the nucleus, and interact in the G-protein system of intracellular signaling (149). It appears that TUB is the only member of this protein family that is implicated in obesity. It is highly concentrated in the nuclei of the hypothalamus that are involved in energy regulation (148). Human *tub* maps to chromosome 11p15. Linkage of human obesity to this cytogenetic region has not been demonstrated, nor have *tub* mutations.

**90.2.1.3 Fatty.** In the fatty (*fat/fat*) mouse, the recessively inherited mutation causes hyperinsulinemia without hyperglycemia, and postpubertal obesity that is less severe than that seen in *ob/ob* or *db/db* mice. The “hyperinsulinemia” is actually due to hyperproinsulinemia. The molecular defect is in the gene encoding carboxypeptidase E (CPE), an endoprotease required for normal processing of prohormones to active hormones, including proinsulin to insulin (150), and for transport and processing of propeptides in the granules of the regulated secretory pathways of the CNS. The primary example of such a peptide is proopiomelanocortin (POMC), which is the precursor for adrenocorticotrophic hormone (ACTH), melanocyte-stimulating hormone (MSH), beta-endorphin, and beta-lipoprotein. POMC has a “sorting signal” consisting of two acidic N-terminal residues, which bind to the two basic residues of CPE. Proinsulin and proenkephalin also attach to this CPE-binding site (151). POMC and proinsulin are then cleaved by prohormone convertase 1 (PC1).

The role of CPE mutations (*fa*) in the expression of the human obesity phenotype is unknown; however, a correlate has been described in which there are mutations of the *PC1* gene (152). This patient has obesity along with impaired processing of insulin leading to diabetes and hyperproinsulinemia, and ACTH deficiency due to impaired processing of POMC. Polymorphic genotypes of the *PC1* gene and neighboring anonymous DNA markers, however, do not confer susceptibility to obesity, NIDDM, or gestational diabetes (153), but may play a role as one of the important polygenes in these syndromes.

**90.2.1.4 POMC.** Since POMC processing defects lead to obesity, it is not surprising that the POMC locus itself is important in body size determination. Two siblings have

been identified with compound heterozygous POMC gene mutations. They had early-onset severe obesity, congenital ACTH deficiency, and red hair pigmentation (154). Both mutations alter the cleavage of POMC, and blood levels of POMC cleavage products (ACTH,  $\alpha$ MSH) were subnormal. The heterozygous parents were unaffected. In genome-wide searches, the region containing the POMC locus is linked to serum leptin levels and fat mass in Mexican-Americans (155,156), and to serum leptin levels in African-Americans (157) and French Caucasians (158). However, POMC coding region and promoter region sequence variants were not related to obesity in Caucasians with juvenile-onset obesity (159). A similar negative association with either extreme of body size was seen when the POMC coding region was screened in patients who were obese, underweight, or with anorexia nervosa (160).

**90.2.1.5 Agouti.** The *yellow* mutation of Agouti mice is a dominant trait which causes yellow coat color (rather than the wild-type hairs which are banded black and yellow), obesity and diabetes. This was the first rodent obesity gene to be cloned, and subsequently over 30 Agouti *yellow* alleles have been identified, which vary in their phenotypic expression. The molecular defect in the most dominant form *Ay* is a deletion in the 5' regulatory region, which brings a different promoter into contact with the coding region. This results in excessive production of Agouti signaling protein (ASP) through ectopic overexpression of normal Agouti mRNA in many tissues, rather than its normal site of expression which is limited to the skin (161). Other Agouti alleles also result from mutations that cause abnormal promoters to be utilized, such as *Aiapy* which has an insertion of retroviral DNA between exons C and D, directing use of an aberrant promoter. This mutation is paternally imprinted. The *Aiy* and *Asy* mutations have insertions upstream of the first coding exon acting as ubiquitous promoters. When transgenic mice overexpress ASP only in the hair follicles of skin, obesity and diabetes are not observed, leading to the hypothesis that these effects are due to a paracrine rather than an endocrine effect of ASP (161). The large number of these dominant Agouti alleles makes it likely that this locus has a propensity toward spontaneous mutations, making it an interesting candidate gene for studies of the genetics of obesity.

ASP and another similar peptide, Agouti-related peptide (AgRP) act as antagonists of native ligand binding to melanocortin receptors 1–4 (MC1R through MC4R), each of which are expressed differentially in specific tissues. AgRP binds specifically to the MC4R in the CNS, and ASP binds to both CNS MC4R and to skin MC1R (162). Transgenic mice with a knockout (KO) mutation of the CNS-expressed MC4R (MC4R-KO) have features of the yellow Agouti phenotype. Both *Ay* and MC4R-KO mice have high levels of NPY expression in an abnormal CNS site, the dorsal medial hypothalamus, which may be an etiologic factor for the obesity phenotype in this

syndrome (163). Mice with MC4R haploinsufficiency have an obese phenotype that is intermediate between wild-type and null mice (164).

**90.2.1.6 Melanocortin Receptors.** Although ASP mutations have not yet been described in humans, several MC4R mutations are now known to be associated with obesity. Two frameshifts, a 4-bp deletion at codon 211 and a 4-bp insertion at nucleotide 732 of the coding sequence, are associated with dominantly inherited obesity (165,166). A novel in-frame deletion of codons 88–92 has been described in one obese female (167). Several other MC4R mutations have been identified among obese cohorts (168,169). Up to 10% of obese subjects in Germany have MC4R mutations (168). The prevalence rate appears to be lower in the United States (170). Functional analyses of several mutations have confirmed their deleterious effects on receptor function (169–171). The codon 88–92 deletion prevents ligand binding (167). The dominant nature of these mutations is presumed to be due to haploinsufficiency as it is in the transgenic mouse model. In one child, homozygous for a 2-bp deletion causing premature termination of MC4R, the obesity phenotype was more severe and of earlier onset than in his heterozygous siblings and parents (172). Interestingly, this child did not have any significant differences in insulin or glucose levels during an oral glucose tolerance test, when compared with 39 BMI/age/sex-matched control children.

In the Québec Family Study, linkage and association analyses showed that both MC4R and MC5R genotypes were related to obesity phenotypes (173). The melanocortin receptor MC3R mutation I183N, identified in a father and daughter with high PBF, alters agonist-induced G-protein activation (174). It does not exert a dominant negative effect on the wild-type receptor, thus is likely to cause its phenotypic effect through haploinsufficiency. In mice with MC3R KO, there is a decrease in food intake and normal energy expenditure, but they have twice the fat mass of their wild-type littermates (174).

## 90.2.2 Energy Expenditure

**90.2.2.1 Hormonal and Genetic Control.** The genetic control of energy expenditure and heat production is an area of intense investigation as many of these metabolic and neuronal pathways are involved in expression of the genetic defects described above. Defects specific to this system are also important as independent contributors to obesity. In rodents, the generation of heat by brown adipose tissue (BAT) is related to the pathways controlling body fat content and distribution. BAT generates heat through its capacity for uncoupling of mitochondrial respiration from oxidative phosphorylation via several mitochondrial uncoupling proteins (UCPs) (175–177). BAT as well as white adipose tissue (WAT) contains the beta adrenergic receptors ( $\beta$ ARs). The  $\beta$ ARs mediate lipolysis in BAT and WAT, as well as mitochondrial

UCP-mediated thermogenesis in BAT. The  $\beta$ 3-AR is thought to be adipose specific, is the predominant subtype in rodent BAT, and can be chronically stimulated by its specific agonists, as opposed to the  $\beta$ 1- and  $\beta$ 2-ARs which become refractory to chronic stimulation (178). In transgenic mice deficient in BAT through targeted disruption of the *UCP-1* gene, obesity develops in the absence of hyperphagia (179). The BAT-deficient mice have enhanced susceptibility to diet-induced obesity and its comorbidities (insulin resistance, hyperglycemia, and hyperlipidemia) (180), which are not reversed by leptin treatment (181). Alternatively, constitutive transgenic overexpression of UCP-1 in both BAT and WAT of mice cause significant reduction in subcutaneous fat, both in normal and genetically obese (*A<sup>y</sup>*) mice (182). Consumption of a high-fat diet can alter UCP gene expression in some mouse strains but not others, indicating variable polygenic control of body composition and thermogenesis (183). In normal rats, UCP protein and mRNA are regulated in a tissue-specific and subtype-specific manner by fasting and by leptin treatment. In some circumstances, the effects on specific UCP subtype protein and mRNA are disparate (184).

In normal mice, there is strain-specific variation in the prevention of high-fat-diet-induced obesity by  $\beta$ 3-AR agonists, which is related to the ability to recruit BAT in WAT anatomic sites (185). Targeted disruption of the  $\beta$ 3-AR gene results in a much milder phenotype than seen in the BAT-deficient mice. They have only modestly increased fat stores (females greater than males), but also have upregulated levels of  $\beta$ 1 but not  $\beta$ 2-AR mRNA in adipose tissue (in BAT more so than in WAT) suggesting crosstalk among the receptor subtypes (186). In WAT of *ob/ob* mice, lipolysis and adenylyl cyclase activation by the  $\beta$ ARs is deficient. Whereas the  $\beta$ 3-AR is the main activator of cyclase activity in WAT of lean mice, it is only partially responsible for adenylyl cyclase activity in *ob/ob* mouse WAT (187,188). In normal rats, the interaction between the sympathetic nervous system, leptin, UCPs, and regulation of fat cell energy utilization is complex. The in vivo modulation of leptin and UCPs appears to depend on sympathetic nerve activity, plasma insulin and glucose, and hemodynamic factors (189).

Variation of the human  $\beta$ 3-AR (ADRB3) gene sequence has been studied extensively, again with disparate results. The human gene has been cloned and its product exhibits properties pharmacologically identical to rodent  $\beta$ 3-ARs (190). In omental fat tissue from obese individuals, there is increased catecholamine-induced lipolysis relative to cells from nonobese subjects, and this effect is mainly due to increased  $\beta$ 3-AR function (191). An ADRB3 missense mutation (Trp64Arg) has been associated with earlier onset of NIDDM and lower resting metabolic rate in Pima Indians (192), abdominal obesity, insulin resistance, and BMR in Finns (193,194), and an increased capacity to gain weight in a French cohort (195). There is no association between this polymorphism and NIDDM

susceptibility in at risk family members (196), obesity phenotypes in the Québec Family Study or in the Swedish Obese Subjects Cohorts (197), obesity and NIDDM susceptibility in Nauruans (198), obesity in Japanese men (199), BMI gained or response to a hypocaloric diet in morbidly obese Finns (200), or obesity in a population of healthy British men (201).

A polymorphism of *UCP-1* (202) is reportedly associated with resistance to weight loss with a low-calorie diet in the French (203), and this polymorphism may have an additive effect with the *ADRB3* polymorphism on rate of weight gain in morbid obesity (204). From a physiologic standpoint, there is no evidence quantifying the amount of BAT in humans, and studies of brown adipocytes from nonhuman primates indicate a lack of functional  $\beta$ 3-ARs (205). In addition, pharmacological characterization of the Trp64Arg-mutant  $\beta$ 3-AR shows no difference in its response to agonists when compared with wild-type receptors in CHO cells (206). In 204 Japanese subjects, the Trp64Arg variant allele was not associated with differences in BMI, plasma glucose or insulin, or family history of obesity or diabetes. However, those with the variant had lower resting autonomic nervous system activity than those without it (207). This conflicting evidence, combined with the mild phenotype in  $\beta$ 3-AR KO mice, would rule against this locus having a major gene effect on obesity. However, a minor effect, when combined with other defects affecting body fat deposition, may contribute to the obesity phenotype.

UCP activity is stimulated by a number of physiologic factors, including cold,  $\beta$ ARs, and fatty acids (208–211). When activated, the protein allows hydrogen ions to “leak” through the respiratory chain of the inner mitochondrial membrane, which abolishes the gradient of hydrogen ions required for ATP synthesis from stored nutrients (209). Mammalian UCP-1 is expressed mainly in BAT, which is present to a significant degree in humans only in the newborn period. The human *UCP-1* gene maps to chromosome 4q31 (210). Human *UCP-2* and *-3* are also expressed in WAT and skeletal muscle (78,208,209), and the genes map to a duplicated locus as adjacent genes on chromosome 11q13 (212,213). *UCP-3* is preferentially expressed in skeletal muscle (212), and has both long and short transcripts (214). In American Pima Indians, BMI is negatively correlated with both the *UCP-3* long and short forms, but not with *UCP-2*. Metabolic rate during sleep correlated positively with the long form of *UCP-3* (214). In the skeletal muscle of *UCP-3* KO mice, there was reduced mitochondrial uncoupling activity. However, there was no effect seen on body weight regulation, exercise tolerance, fatty acid oxidation, or cold-induced thermogenesis (215).

A *UCP-1*-associated Bcl-I RFLP may be associated with increased body size (202). Seven sequence variants of the *UCP-1* gene were identified in Danish subjects, but genetic variation in the coding region of the gene did not contribute to obesity in this population (216). There is

no association between *UCP-2* genotypes and obesity in French Caucasians (217). Allele frequencies of a *UCP-2* gene polymorphism at codon 55 (A55V) were similar in African-Americans and Caucasian Americans (218), but its association with body size was not characterized. A 45-bp insertion polymorphism of the 3′ flanking region of the *UCP-2* gene is correlated with high BMI and %BF in children (219). This insertion/deletion polymorphism results in mRNA species of different lengths, and the insertion variant is less stable. The insertion variant is in linkage disequilibrium with a pair of linked promoter region sequence variants (T/A at –2723 and G/A at –866). The minor allele –866A is associated with a decreased risk of obesity in middle-aged subjects from Austria (220). Regarding *UCP3*, an exon 5 C–T substitution that does not change the codon 210 Tyrosine residue was associated with significantly lower resting energy expenditure in African-American but not White women (221). There were no effects of genotypes of three other *UCP-3* variants, nor of two *UCP-1* and two *UCP-2* variants. In a review of over 40 studies of UCP gene variants in humans, *UCP-1* was not felt to contribute significantly to variability in BMI. However, *UCP-2* and *UCP-3* effects on BMI are accepted. As they are adjacent genes, it is likely that their genetic variants are in linkage disequilibrium, and the effects of one gene on BMI may reflect variants in the other (222).

### 90.2.3 Control of Feeding

Energy intake and expenditure is under the control of complex interactions between peripheral signaling and effector systems (e.g.  $\beta$ ARs and UCPs discussed above) and neuroendocrine systems (162,223). There is great complexity in these interactions (224), and the details of these pathways are under widespread investigation. Some of the pathways are illustrated in Figure 90-4. The contribution of signals from the gastrointestinal tract represents the more acute responses to feeding, rather than the chronic responses to energy stores (225). Among these are ghrelin from the stomach, insulin and glucagon from the pancreas, and PYY and glucagon-like peptides from the intestinal tract. The factors important in determining an individual’s set point for food intake may change as individuals become obese because of attenuation of leptin signaling induced by increasing adiposity (128).

**90.2.3.1 Ghrelin.** Ghrelin was first discovered in the 1970s as a growth hormone secretagogue. Its major role, however, is not modulation of growth hormone secretion from the anterior pituitary, but rather its role in increasing energy stores is felt to be more important, physiologically (226). It is secreted mainly by the stomach, with minor contributions from the brain, kidney, and placenta. These other sources may compensate for gastric secretion as patients having gastrectomies only have 65% reductions in blood levels. Serum levels are inversely correlated with BMI but are paradoxically elevated in children with the

**FIGURE 90-4** Interactions that regulate food intake and body fat mass. Dashed lines: inhibitory effects. Solid lines: stimulatory effects. PWS (227). Ghrelin levels are high in anorexia nervosa, and levels drop after food intake in lean subjects. However, in obese subjects, the levels do not drop after eating (228). Ghrelin binds to specific receptors in the hypothalamus on NPY/AgRP neurons, and acts to some degree as a stimulator of hunger (225). Despite evidence that suggests a potentially strong influence of ghrelin on body size, ghrelin-deficient mice created by gene KO are the same as their wild-type littermates in terms of size, growth rate, food intake, response to fasting, body composition, and reproduction (229). In humans, variation in the ghrelin gene was associated with higher BMI and lower insulin response to glucose in a group of 70 tall obese children (230). Other evidence points to a genetic contribution of ghrelin to body size, including a study showing that ghrelin levels at baseline and in response to overfeeding, are more similar in monozygotic than dizygotic twins (231).

**90.2.3.2 Central Control of Feeding and Energy Expenditure.** The hormone leptin is made almost exclusively in peripheral (mainly adipose) tissues, and acts centrally in the hypothalamus by modifying two major effector systems. Low plasma concentrations of leptin and insulin (e.g. during weight loss) increase food intake and decrease energy expenditure by stimulating NPY synthesis, and perhaps by inhibiting sympathetic activity and other catabolic pathways. High leptin and insulin concentrations (e.g. during feeding and weight gain) decrease food intake and increase energy expenditure through release of melanocortin and corticotropin

releasing hormone (CRH), among others (232). The list of neuropeptides which are known to alter energy balance is growing rapidly. Some of these are listed in Table 90-3.

**90.2.3.3 Neuropeptide Y.** NPY is a neurotransmitter that is abundant in the hypothalamus, and may be important in mediating obesity. Hypothalamic levels of NPY and its message are elevated in *ob/ob* mice, *db/db* mice, and *fafa* rats. Central administration of NPY to lean rats causes hyperphagia, obesity, insulin resistance and increased triglyceride deposition in WAT. These effects are prevented by adrenalectomy before NPY treatment (233). In a special strain of *ob/ob* mice that are deficient in NPY, the obesity and hyperphagia are less severe, infertility is less marked, and diabetes is seen later and is milder than in *ob/ob* mice with intact NPY (234). Otherwise, normal mice homozygous for NPY KO mutations have normal fed and fasting plasma levels of leptin, thyroxine, corticosterone, and sex steroids, indicating NPY is not vital for normal pituitary function (235). They also have lower seizure thresholds and higher ethanol consumption and tolerance. However, after a fasted state, NPY KO mice have less food intake than WT mice, have anxiogenic-like behavior, and hypoalgesia (236). NPY receptor 1 KO mice have marked obesity (159), but NPY receptor 5 KO mice have a less severe obesity phenotype (237).

In human studies, iv NPY administration increases sleep and decreases ACTH release in males (238).

**TABLE 90-3 Central Nervous System Proteins (Neuropeptides) Involved in Energy Homeostasis**

Neuropeptide	Regulation by Leptin or Insulin
<b>Orexigenic (stimulates feeding)</b>	
Neuropeptide Y <sup>a</sup>	Decreased
Agouti-related peptide <sup>a</sup>	Decreased
Melanin concentrating hormone	Decreased
Orexin A and B (Hypocretin 1 and 2)	Decreased
Galanin	Decreased
<b>Anorexigenic (inhibits feeding)</b>	
Leptin	
α-Melanocyte-stimulating hormone <sup>a</sup>	Increased
Corticotropin releasing hormone <sup>a</sup>	Increased
Thyrotropin releasing hormone <sup>a</sup>	Increased
Cocaine- and amphetamine-regulated transcript (CART) <sup>a</sup>	Increased
Interleukin-1β <sup>a</sup>	Increased
Urocortin <sup>a</sup>	
Glucagon-like peptide 1	
Oxytocin	
Neurotensin	
Serotonin	
Somatostatin	

<sup>a</sup>Effects both energy intake and expenditure that change energy stores.

<sup>b</sup>β-endorphin treatment stimulates feeding in many animal models, but β-endorphin knockout male mice have hyperphagia and obesity.

<sup>c</sup>Most ghrelin is secreted from the stomach, but some is produced in the hypothalamus.

Information obtained from Schwartz et al. (232), and Sahu (413).

Genetic studies of the human genes encoding NPY have identified no deleterious mutations. Linkage analysis of the *NPY* gene showed evidence of linkage to body size in Mexican-American obese sib pairs (239), but not in French Caucasian obese families (240).

The NPY Y1 and Y5 receptors are transcribed from a common promoter region in opposite directions, suggesting they evolved from a gene duplication event (241). Linkage and association studies with these genes have failed to identify an effect on body size in several populations (239,240,242).

**90.2.3.4 Orexins.** Orexins A and B are stimulators of feeding that are secreted as preprohormones by the hypothalamus. They act through binding to orexin receptors, which are of the classical G-protein-coupled seven transmembrane domain class (243). Orexin KO mice have narcolepsy (244), a finding that may correlate with NPY-induced sleep in humans, described above. Human orexin receptors are localized in the pituitary gland (245) and in pheochromocytomas (246). Mutational analyses and linkage studies of the genes encoding these peptides have not yet been reported in humans with altered body size.

### 90.2.3.5 The Hypothalamic–Pituitary–Adrenal (HPA) Axis in Feeding and Body Size Determination.

It has been demonstrated in multiple animal models that adrenalectomy obliterates or attenuates the obesity syndromes expressed in genetically obese rats and mice, in diet-induced obesity, and in hypothalamic obesity (233). Replacement of only trace quantities of glucocorticoid to these adrenalectomized animals causes prompt return of the phenotypes indicating heightened sensitivity to the steroid. In humans and animals with hypercortisolemia, obesity is prominent. However, in adrenalectomized animals, the effects seen could result from a combination of glucocorticoid deficiency alone or in combination with the secondary elevation of hypothalamic CRH and pituitary ACTH production. Obese Zucker (*fa/fa*) rats have no difference in hypothalamic levels of CRH or in magnitude of CRH response to stressors when compared to lean littermates. However, basal secretion of CRH is less in the obese rats, and CRH response to adrenalectomy is more pronounced in the obese rats. Corticosterone infusion is more effective in suppressing CRH levels in adrenalectomized obese rats than in adrenalectomized controls (247), leading to the hypothesis that *fa/fa* rats have an abnormality of the HPA axis at a site proximal to that which mediates glucocorticoid responsiveness. Central administration of CRH as well as a related hormone, urocortin (248,249), mimics the events seen in the “stress response” including anorexia. This treatment prevents excessive weight gain in *fa/fa* rats when compared with pair fed *fa/fa* controls (250,251).

Leptin treatment of normal mice and rats causes a blunted HPA axis response to stress, perhaps via decreased release of CRH (252). In *A<sup>y/a</sup>* obese mice, the effects of POMC and leptin pathway activation are additive, yet independent (253). Full-length *LEPR* message has been identified in human adrenal cortex, and to a lesser degree in adrenal medulla. In cultured adrenal cells, leptin inhibited ACTH-stimulated cortisol, aldosterone, and dehydroepiandrosterone secretion (254). In addition, some individuals may have heightened sensitivity to glucocorticoid because of a sequence variant of the glucocorticoid receptor gene, which has been associated with higher BMI and lower bone density in the Rotterdam Study (255). These data suggest that therapeutic manipulations of the HPA axis could alter the phenotype of certain genetically obese individuals.

One of the most interesting developments in this area is the role of adipose tissue in the synthesis and degradation of cortisol through the action of 11β-hydroxysteroid dehydrogenase (11β-HSD). 11β-HSD2 converts cortisol to its inactive metabolite cortisone. In the kidney, this prevents activation of the mineralocorticoid receptor by cortisol, which is present in plasma in much higher concentrations than its native ligand, aldosterone. Cortisol has equal affinity for the receptor, and aldosterone is not a substrate for the enzyme. If 11β-HSD2 is deficient,

the syndrome of apparent mineralocorticoid excess occurs (256). Glycyrrhetic acid in licorice causes salt retention and hypertension because it inhibits  $11\beta$ -HSD2 activity (257). Topical administration of glycyrrhetic acid in females caused reduction in the underlying femoral subcutaneous fat (258), presumably by causing a local reduction in adipose tissue cortisol. Chronic ingestion of licorice was associated with a reduction in fat mass in 15 normal-weight young adults, without a change in BMI or in caloric intake (259).

$11\beta$ -HSD1 (cortisone reductase) converts cortisone back into cortisol in the liver. Defects in  $11\beta$ -HSD1 activity have been implicated in several clinical settings (260,261). There is mounting evidence that increased  $11\beta$ -HSD1 activity in visceral adipose tissue contributes to obesity and the metabolic syndrome. Transgenic mice that overexpress  $11\beta$ -HSD1 in adipose tissue develop the typical metabolic syndrome, with visceral obesity exaggerated by a high-fat diet, insulin-resistant diabetes, hyperphagia, hyperleptinemia, and hyperlipidemia (262). Patients with hypothalamic obesity may have increased  $11\beta$ -HSD1 activity (263), and adipose tissue of individuals with idiopathic obesity has been shown to have higher than expected  $11\beta$ -HSD1 activity (264,265).

The human gene encoding  $11\beta$ -HSD1 contains two polymorphic intronic microsatellites, and one intronic polymorphism useful for linkage and association studies. In a study of 439 normal adults from Glasgow, and of 557 Danish military draftees (234 with juvenile-onset obesity and the rest normal controls), there was no significant association of  $11\beta$ -HSD1 genotypes with BMI in either group, but there were weak associations between  $11\beta$ -HSD1 activity and waist-to-hip ratio (266). In American children, the intronic ins4436A polymorphism was associated with BMI and insulin resistance (267).

#### 90.2.4 Adipose Tissue Development and Function

Adipose tissue is a biologically active organ, involved not only with energy storage and release but also with autocrine and paracrine effects that are widespread (268). These effects are manifested in endocrine/hormonal function, immune function including its role in cardiovascular risk, and the CNS communication through leptin, tumor necrosis factor alpha (TNF $\alpha$ ), interleukin 6 (IL6), adiponectin, resistin, and other adipokines. Leptin and adiponectin are thought to be insulin sparing in their effects, whereas TNF $\alpha$ , IL6, and resistin are thought to contribute to the insulin resistance phenotype associated with obesity (268,269).

Adipocytes play a pivotal role in the maintenance of energy balance. The roles of BAT, WAT, sympathetic nervous system signals, and UCPs were discussed in Section 90.2.2. The development of mature adipose tissue from

preadipocytes is accompanied by a marked increase in the expression of adipose-related transcripts such as leptin and UCPs. The terminal differentiation of adipocytes is controlled by several transcription factors, one of the more important being peroxisome proliferator-activated receptor- $\gamma$ 2 (PPAR- $\gamma$ 2). After differentiation, the fat cells produce many products other than metabolic fuels that are secreted into the circulation. Prominent examples of these include the cytokines leptin (discussed in Section 90.2.1) and TNF $\alpha$ . In addition, adipocyte macrophage colony-stimulating factor has been shown to be important in stimulating adipocyte hyperplasia (270). Hormone-sensitive lipase (HSL) stimulates breakdown of triglycerides into fatty acids, which have been implicated in the development of insulin resistance. The gene encoding human *HSL* maps to chromosome 19q13, and contains a dinucleotide repeat polymorphism within one of its introns. This polymorphism was associated with obesity and type 2 diabetes in a French population (271).

**90.2.4.1 PPARs.** Members of the PPAR family of nuclear receptors regulate adipocyte differentiation. PPARs are divided into subtypes  $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ , each of which is expressed in a tissue-specific manner. The PPAR- $\gamma$  class is expressed in adipose tissue, and has two isoforms,  $\gamma$ 1 and  $\gamma$ 2, which are differentially spliced products of the same gene. The PPAR- $\gamma$ 2 isoform is the longer protein, and is adipose specific (272). When PPAR- $\gamma$ 2 binds its ligands (prostaglandin derivatives, fatty acids, and thiazolidinediones), it forms a heterodimer with the retinoid X receptor that activates a cascade of fatty acid metabolism and preadipocyte differentiation (272–274). This effect is adipose-depot specific (273), and can even occur in fibroblasts (274). Homozygous *PPAR $\gamma$*  KO mice have a prenatal lethal phenotype due to placental dysfunction. Heterozygous mice seem to be protected from the development of insulin resistance, and have reduced fat mass, smaller adipocyte size, and hypersecretion of leptin (275). Mice that have a muscle-specific KO of *PPAR $\gamma$*  had normal responsiveness to thiazolidinediones, as well as normal glucose and insulin levels, despite excess adiposity with reduced caloric intake. However, they have whole-body insulin resistance when tested with a hyperinsulinemic euglycemic clamp, due to localized insulin resistance in nonmuscle tissues (liver, and perhaps, fat) (276).

The human gene encoding PPAR- $\gamma$ 2 has been cloned, and maps to chromosome 3p25 (277). Several sequence variants have been described, and as with other candidate genes for obesity, studies in human populations have revealed differing results. A Pro115Gln variant was shown to accelerate differentiation of murine fibroblasts into adipocytes when it was over expressed (278). This variant was identified more frequently in German obese subjects than nonobese subjects (278). However, this variant was not found in a different study of German subjects (279), nor in Danish men (280). Another more widely studied variant, Pro12Ala, has also shown both

positive and negative correlations with obesity. It was initially studied and ruled out as a candidate gene for lipotrophic diabetes (277). *PPAR-γ2* Pro12Ala occurred with the same gene frequency in obese and lean German subjects (279). Association studies with two different Caucasian populations revealed a positive relationship between Pro12Ala and high BMI (281). In French subjects, studies of this variant suggested a role for it in weight control and lipid homeostasis, but not in the etiology of type 2 diabetes (282). Among patients with type 1 and type 2 diabetes, the variant had no effect on lipids or BMI (283). In Mexican-Americans from the San Antonio Heart Study, presence of the Pro12Ala allele was positively associated with BMI and serum leptin levels (284). A large study of Danish men underscores the conflicting nature of these study results. Obese Danish men who were homozygous for Pro12Ala had higher BMI and higher weight gain than wild-type carriers. However, homozygotes for Pro12Ala in the control group had a lower BMI and less weight gain than the wild-type carriers (280).

**90.2.4.2 TNFα.** TNFα is one of the several cytokines, including leptin, interleukin 1 and 6, interferon, and TNFβ, known to have profound effects on lipid metabolism. It not only is secreted by adipose tissue but also has direct effects on adipocyte metabolism (285). These effects are mostly catabolic, including suppression of many lipogenic enzymes, and development of insulin resistance (285). TNFα inhibits human adipose cell insulin signaling (286) and causes apoptosis in human adipose cells (287), and in rat brown adipocytes (288). TNFα stimulates leptin release from cultured human adipocytes (289), and levels of the soluble TNFα receptor (sTNFα-R55) are positively correlated with plasma insulin and leptin levels in patients with type 2 diabetes and in controls (290). TNFα infusion in humans induces an increase in serum leptin levels in humans (291). KO mice that are deficient in the adipocyte fatty-acid-binding protein aP2 are equally susceptible to diet-induced obesity as are control mice. However, the aP2 null mice fail to express TNFα, and also failed to develop the insulin resistance seen in the obese control mice (292).

TNFα KO mice did not have a significant change in body size by 28 weeks of age, but there was an increase in insulin levels, and a decrease in triglyceride, leptin, and glucose levels (293). In mice with gold thioglucose-induced obesity, TNFα deficient animals had lower levels of glucose and insulin, and lower insulin and glucose responses to a glucose tolerance test than the obese wild-type animals (293). In KO mice simultaneously deficient for both the p.55 and p.75 types of the TNFα receptor, obesity and diabetes were present. However, KO of either receptor alone did not produce this phenotype, and *db/db* mice lacking p.55 were still diabetic and insulin resistant (294).

The human TNFα gene maps to chromosome 6p21, within the region containing the class 3 major

histocompatibility locus and the steroid 21-hydroxylase genes (295). Polymorphic dinucleotide repeat markers that map near TNFα were genotyped in American Pima Indian families. The marker closest to TNFα was linked to %BF in a sib-pair analysis, and was associated with BMI by analysis of variance (296). However, screening of the TNFα coding region and promoter identified only a single polymorphism, and this was not associated with obesity in this population. A G–A substitution at position –308 in the TNFα promoter, which causes a restriction fragment length polymorphism (RFLP) with the enzyme NcoI, was associated with a higher rate of transcription of TNFα in vitro. In Spanish overweight individuals, this RFLP was associated with %BF, insulin sensitivity, and leptin levels, despite no differences in BMI and plasma TNFα levels (297).

**90.2.4.3 Adiponectin.** Adiponectin is a peptide secreted by adipose tissue, and is preferentially secreted by mature adipocytes over preadipocytes (298). It was originally termed Acrp30 (adipocyte complement-related protein of 30 kDa), because of its homology to complement factor C1q. It was also known as adipocyte most abundant gene transcript 1 (apM1), having been isolated as the most abundant mRNA in human adipose tissue (299). Plasma levels are strongly positively correlated with insulin sensitivity, and it has putative antiatherogenic properties (298). Plasma levels are the reverse of those of leptin—adiponectin concentrations are lower in obese than lean subjects (300). Its gene expression in and secretion from 3T3-L1 adipocytes is reversibly inhibited by interleukin 6, an adipocytokine that is elevated in states of insulin resistance (301). In mice, intravenous injection of adiponectin was followed by a rise in CSF levels, consistent with transport to the CNS. Intracerebroventricular administration of adiponectin in these animals caused a decrease in body weight, due to an increase in energy expenditure (302).

The adiponectin gene spans a 17-kb region on human chromosome 3q27, and contains three exons and two introns (303). Several polymorphisms of the gene have been detected and analyzed in human subjects (303,304). A conservative G/T substitution in exon 2 did not correlate with plasma adiponectin levels or with the presence of obesity in Japanese subjects (304), but was associated with serum cholesterol and waist circumference in obese Swedish subjects (305). In the latter study, the frequencies of the G or T allele did not differ between obese and lean subjects. In obese subjects undergoing gastric banding surgery, genotype haplotypes of two linked polymorphisms 11,377 C/G and 11,391 G/A correlated with adiponectin levels at baseline (306).

**90.2.4.4 Visfatin.** Visfatin is one of the members of the adipokine group. It was formerly known as pre-B-cell colony-enhancing factor (PBEF), and also small-molecule insulin mimetic compound 2 (307,308). This nonpeptidic activator of insulin receptor action is secreted by visceral fat as well as lymphocytes. Plasma levels in

humans and in mice correlate positively with the quantity of visceral fat but not subcutaneous fat (309). Treatment of mice with this compound reduces food intake and prevents high-fat-diet-induced obesity (310). When mice with diabetes are treated with recombinant visfatin, their diabetes improves whether they have type 2 or streptozocin-induced diabetes. Homozygous visfatin KO is a prenatal lethal mutation, and heterozygous mutants have a diabetic tendency but no change in body fat (309). Studies of variation in the human gene for visfatin may provide insight into the link between visceral adiposity and type 2 diabetes.

### 90.2.5 Gene Targeting and Effects on Body Fat/Feeding

The widespread use of gene targeting to study a myriad of genes has been applied extensively to the study of obesity. Many examples of these animal models have been described above. These, along with other relevant animal models are summarized in Table 90-4, and they demonstrate both monogenic and polygenic effects on body size variables.

### 90.2.6 Polygenic Models

The polygenic mouse models of obesity have allowed identification of multiple autosomal and nonautosomal QTLs within individual strains, which modify obesity, plasma cholesterol levels, specific deposition of body fat depots (311–314) and propensity toward development of high leptin levels and obesity on a high-fat diet (315,316). To underscore the complexity of the contribution of genetic background to autosomal-recessive obesity, obese Zucker (*fa*)/NKY13H intercross F2 rats have at least three QTLs unrelated to *Lepr* that control BMI and glucose homeostasis (317). In addition, heterozygosity for *Lep<sup>ob</sup>* and *Lep<sup>db</sup>* in mice is known to affect body composition and leptin homeostasis (123). Polygenic models may more closely resemble the human obesity phenotypes, however, the single gene defects producing recessive traits, dominant traits, promoter alterations, and those subject to parental imprinting must continue to be considered candidates for genetic effects in human obesity (224).

### 90.2.7 Gene–Environment Interactions

There are a number of examples of environmental factors influencing genotype expression. Consumption of a high-fat diet can alter *UCP* gene expression in some mouse strains, indicating variable polygenic control of body composition and thermogenesis (183). In normal mice, there is strain-specific variation in the prevention of high-fat-diet-induced obesity by  $\beta$ 3AR agonists, which is related to the ability to recruit brown adipose tissue in white adipose tissue anatomic sites (185). In

humans, physical activity may counteract the obesity related to specific genotypes of the beta 2 adrenergic receptor  $\beta$ 2AR gene (318). The  $\beta$ 3AR (319) and lipoprotein lipase (*LPL*) genes (320) may be involved in similar interactions. Both  $\beta$ 2AR- and  $\beta$ 3AR-mediated effects involve interactions with UCPs in their production of thermogenesis and response to high-fat diets (321). Other loci that may impact individual responses to increased energy intake include *ApoE*, *ApoA-II*, and the LDL receptor (322). These and other as-yet uncharacterized interactions would be important in predicting the responses to prevention strategies or treatments for obesity.

### 90.2.8 Nonmammalian Models

While the above discussion has focused on rodent models, nonmammalian animal models are also playing an increasing role in the investigation of obesity and related traits. These nonmammalian animal models have several advantages over rodents, including shorter generation times, ease of breeding, large population size and the existence of tools for the creation and screening of mutants and phenocopies on a large scale. Some highlights of genetic findings in nonmammalian models are listed below.

**90.2.8.1 *Drosophila*.** Mutations in the Laminin A (*LanA*) gene, a fruit fly gene that is closely related with the human *LAMA5* gene, lead to a decrease in triacylglycerol storage, body weight and total protein content (323). The human *LAMA5* gene maps to a well-replicated obesity-linkage region on chromosome 20q13.2–q13.3 and variants may play a role in body composition and lipid phenotypes (324). Other studies indicate that members of the syndecan gene family may play a role in energy metabolism and regulation of body weight in *Drosophila* and that variants in homologous human genes may influence the same phenotypes in humans (325). Further studies are needed to confirm if these genes play a role in human obesity and to elucidate the mechanisms involved in any such role.

**90.2.8.2 Zebrafish.** Zebrafish are being used to study the effects of KO or knockdown of various genes involved in obesity and metabolic regulation (326) and may provide a means of interrogating known obesity-related genes as well as the discovery of novel genes in the future.

**90.2.8.3 *Caenorhabditis elegans*.** *C. elegans* provides an excellent model for the study of the basic biology of obesity and energy regulation (327). Genes identified in human genetic studies can be knocked down or mutated in *C. elegans* to study their physiology, and conversely, targeted mutagenesis and screening of mutants can reveal novel genes involved in energy metabolism and the regulation of adiposity (328). For example, the *Indy* (I am not dead yet) gene was shown to regulate lifespan and adiposity phenotypes in *Drosophila* and *C. elegans* and this finding was later replicated in rodents using a mouse KO (329).

## 90.3 MENDELIAN DISORDERS ASSOCIATED WITH INCREASED BMI IN HUMANS

Increased risk of obesity can, in relatively rare cases, be secondary to single gene disorders of large effect. While these disorders are uncommon, they do shed light on some of the complex hormonal and neural networks that regulate adiposity. Their murine models, physiological role and known counterparts in humans have been discussed in detail in Section 90.2.1. Here

we will briefly review known human genetic defects and their clinical features.

### 90.3.1 Leptin Deficiency

Missense and nonsense mutations in the leptin gene are an extremely rare cause of morbid obesity. Leptin deficiency is inherited in an autosomal-recessive manner and leads to early-onset extreme obesity characterized by intense hyperphagia. Resting and free-living energy expenditure is normal. Patients also have hypogonadotropic hypogonadism with delayed spontaneous puberty, immune deficiency and may have other neuroendocrine defects (e.g. hypothyroidism) (330). They respond dramatically to treatment with recombinant human leptin, with resolution of hyperphagia and associated phenotypes (331,332). Recently, a patient with a leptin mutation and relatively mild obesity and hypogonadotropic hypogonadism has been described, raising the possibility that milder clinical forms of leptin deficiency may also exist (333).

**90.3.1.1 Leptin Receptor Mutations.** Human leptin receptor deficiency was initially reported in a single family with very severe early-onset obesity and growth retardation secondary to impaired growth hormone secretion. Since then, it has been found that mutations in the leptin receptor may be present in up to 3% of the cases of morbid obesity (334). These subjects presented with early-onset hyperphagia and morbid obesity without significant elevation of leptin levels or developmental abnormalities or dysmorphism.

**90.3.1.2 MC4R.** Defects in the melanocortin 4 receptor may be the most common form of monogenic obesity in humans. These mutations appear to be codominant, with more severe obesity seen in homozygotes. Prevalence of MC4R mutations ranges from 1% to 6% in morbidly obese patients (335), but has not been confirmed in all populations (336,337). Functional studies of these mutants have confirmed the deleterious effects in many cases (167,171). Nonpathogenic mutations and mutations that exert only a mild effect on BMI are more common than mutations associated with morbid obesity, making genetic diagnosis relatively complicated in these cases (335).

**90.3.1.3 POMC Mutation.** POMC is processed to produce the hormones ACTH, MSH alpha, beta and gamma, and beta-endorphin. Defects in POMC are an extremely rare cause of obesity, ACTH deficiency and red hair (154) though mutations that were not associated with red hair have also been reported (338,339).

**90.3.1.4 PC1 Mutation.** PC1 cleaves prohormones before processing by carboxypeptidase. A mutation in PC1 has been described a patient with obesity, elevated proinsulin, hypocortisolism, hypoglycemia, hypogonadotropic hypogonadism and elevated POMC (152). In at least one case, a mutation in PC1 was also associated with neonatal diarrhea and malabsorption (340).

**90.3.1.5 Cohen Syndrome.** Mutations in the *VPS13B* gene (vacuolar protein sorting 13, yeast, homolog B), located on chromosome 8q22, are associated with Cohen syndrome. Cohen syndrome is characterized by truncal obesity, thin extremities and short stature and is inherited in an autosomal-recessive manner (341).

**90.3.1.6 Alstrom Syndrome.** Alstrom syndrome (ALMS) is an autosomal-recessive ciliopathy that is characterized by truncal obesity, short stature, retinal cone dystrophy, progressive hearing loss, dilated cardiomyopathy, type 2 diabetes and progressive pulmonary, hepatic, and renal dysfunction. The involved gene, *ALMS1*, is located on chromosome 2p13 and encodes a large protein that is involved in ciliary function (342). How and why a ciliopathy causes obesity is the focus of intense research and may shed new light on the regulation of adiposity and energy metabolism in humans (343).

**90.3.1.7 Others.** Individual cases of mutations in several other genes involved in the CNS appetite regulation and the development of neuronal circuits have been described in patients with morbid obesity, e.g. in *SIM1* (single-minded, *Drosophila*, homolog of, 1) gene (344) and *NTRK2* (neurotropic tyrosine kinase receptor 2) gene (345).

## 90.3.2 Syndromic Obesity

Syndromic obesity describes obesity that is associated with well-defined combinations of other phenotypes such as mental retardation, dysmorphic features and other developmental abnormalities. Examples of such syndromes with their known genetic cognates include the following.

**90.3.2.1 Prader-Willi Syndrome.** PWS is the most common obesity syndrome with an incidence of 1/15,000–1/25,000 live births. It is caused by loss of expression of paternally expressed genes in the imprinted (differentially methylated) 15q11–13 region. This loss may be secondary to deletions of the paternal 15q11–13 region (70–75% of cases), maternal uniparental disomy of chromosome 15 (20–25%), microdeletions in the imprinting center at the *SNURF-SNRPN* gene locus (<3%) and paternal translocations (<1%) (346). Diagnostic testing is best performed by analyzing the methylation status of the PWS region using methylation-specific PCR. The clinical features of PWS include low birth weight, severe hypotonia and feeding difficulties in early infancy, followed by hyperphagia and obesity starting in early childhood. Other characteristic features include hypogonadism, short stature, small hands and feet, facial dysmorphology (narrow bifrontal diameter, almond-shaped eyes, triangular mouth) and a distinctive behavioral phenotype (347). The 15q11–13 region in an imprinted region in which at least 10 genes are only expressed from the paternal chromosome and these were therefore considered candidate genes for PWS (348).

Some of the variations in clinical phenotypes between different PWS patients are due to variation in the number of deleted or silenced genes in this region. But while several genes contribute to the phenotype, deletion of genes involved in the production and processing of small nucleolar RNAs, particularly snoRNA SNORD116 cluster (*HBII-85*) appear to be sufficient to cause the core phenotypes of PWS (349).

**90.3.2.2 Bardet-Biedl Syndrome.** BBS is a rare syndrome characterized by early-onset obesity, rod-cone dystrophy, dyslexia, learning disabilities, postaxial polydactyly, hypogonadism and progressive renal disease. The McKusick-Kaufman syndrome is an allelic form of BBS. It was initially thought to be a classic autosomal-recessive disorder, but the genetics of BBS turn out to be much more complex, with at least 15 different genes now identified as being associated with this syndrome (350,351). Some behave in an autosomal-recessive manner, but others are “triallelic,” requiring a homozygous recessive mutation in one gene and an additional mutation at a second locus. Most of these genes are involved in ciliary function and the syndrome is now considered ciliopathy that overlaps clinically with ALMS (352). Its recurrence risk depends on the specific locus containing genetic mutation of each pedigree (353).

**90.3.2.3 WAGR Syndrome.** Wilms' Tumor, aniridia, genitourinary abnormalities and mental retardation (WAGR) syndrome is associated with heterozygous interstitial deletions of chromosome 11p-13. This syndrome included obesity in some but not all patients and comparison of the deleted regions between obese and nonobese patients indicated that obesity is associated with deletion of the brain-derived neurotrophic factor (*BDNF*) gene (354). Polymorphisms in the same gene have since been found to be associated with obesity in GWAS cohorts. This gene is expressed in the CNS and appears to be involved in the regulation of appetite.

**90.3.2.4 16p11.2 Deletions.** Deletions in this region are associated with obesity and in some cases with autism. This region includes the gene *SH2B1*, which codes for an adapter protein involved in tyrosine kinase signaling including leptin and insulin signaling (355).

## 90.3.3 Polygenic Obesity

In most cases, the inherited risk of obesity appears to be complex and is very likely polygenic in origin. It remains a matter of dispute if this risk is due to rare variants of large effect or common variants of small effect. At the dawn of the genomic era, it was generally assumed that common variants, each of small effect, are responsible for the main genetic contribution to risk of obesity. But very large genome-wide association studies (GWAS) have explained a relatively small proportion of the genetic risk of obesity and some researchers have proposed that this may be due to the fact that rare variants of large effect that arise relatively recently in extended families or clans

are responsible for a large proportion of the hereditary risk of obesity (62).

**90.3.3.1 Linkage and Candidate Gene Studies of the Genetics of Human Obesity.** Starting in the 90s, several research groups attempted to identify genes associated with obesity using candidate gene and linkage studies. Genes thought to be involved in appetite regulation, partitioning of body fat, energy storage, energy expenditure and other physiologic processes that could play a role in obesity were investigated to see if variants in their sequences were linked to risk of obesity. Linkage studies using minisatellites and other markers were used to identify genomic regions that appeared linked to BMI variation. Among the regions and genes found to be possibly linked to obesity were a region on chromosome 3 that included the adiponectin gene as well as other genes that were previously not known to be involved in the control of body composition or energy metabolism (e.g. *PSARL* and *VPS8*) (356). Overall, the results of these studies were somewhat disappointing and did not explain most of the genetic risk of obesity.

**90.3.3.1.1 GWAS in Humans.** With advancements in technology, it has become feasible to genotype hundreds of thousands to several million SNPs in individual microarrays and to test their association with obesity and related traits. The first large GWAS in humans led to the identification of *FTO* (Fat Mass and Obesity associated gene) as a gene that is associated with variation in BMI in almost every population studied to date (357). Since then, large GWAS and meta-analyses have identified dozens of new genes and intergenic loci associated with BMI, while also replicating many of the genes identified earlier by candidate and linkage studies (Table 90-5) shows many of the genes found to be associated with obesity in GWAS. We will discuss a few of these in greater detail:

**90.3.3.1.2 *FTO*.** *FTO* (Fat mass and obesity associated) is a large gene, over 400 kb in size, and several different SNPs in the first intron have been robustly associated with obesity in at least 22 different population groups (358). The effect size is modest (3 kg increase in weight in individuals homozygous for the risk allele) but the risk allele is prevalent at a level of almost 50% in the Caucasian population, so the gene may still contribute to obesity in a very large number of individuals. When it was initially discovered, nothing was known about its function, let alone its role in the regulation of BMI. Since then, it has been discovered that the *FTO* gene product is an oxoglutarate-dependent demethylase that is able to bind and demethylate single-stranded DNA and RNA. How this relates to regulation of body weight remains unknown at this time.

The first complete *Fto* null mouse (*Fto*<sup>-/-</sup>) was reported in 2009. The homozygote displayed a phenotype that includes growth retardation, decreased fat mass and lean mass, increased metabolic rate and increased food

intake after correction for lean body mass. Heterozygotes, interestingly, are resistant to high-fat-diet-induced obesity (359). A different mutation that causes partial loss-of-function of the *FTO* gene is associated with decreased fat mass and increased energy expenditure, but no hyperphagia or growth retardation is seen (360). The *FTO* gene is widely expressed in the body, with high levels of expression in the CNS and particularly in the hypothalamus. Overexpression of *FTO* in the arcuate nucleus in mice leads to a reduction in daily food intake, while knocking down its expression leads to increased food intake (361).

The effects of an *FTO* mutation in humans have been studied in one extended family and all affected homozygotes suffered from a polymalformation syndrome that includes postnatal growth retardation, microcephaly, severe brain deficits, dysmorphic facies, cardiac abnormalities and cleft palate and all affected members died within the first 30 months of life. Heterozygotes in the extended family have not been studied in detail, but no overt body weight phenotype has been reported. Thus, *FTO* appears to be essential for the normal development of a number of major organs and a complete lack of *FTO* activity is incompatible with life beyond early childhood.

The physiological role of *FTO* in body-weight regulation remains unknown at this time. The *FTO* protein may play a role in appetite regulation as well as resting energy expenditure. As it is capable of demethylating both DNA and RNA (362), it may be involved in epigenetic modulation of DNA as well as in the regulation of various RNAs.

**90.3.3.1.3 Peroxisome Proliferator-Activated Receptor Gamma Gene (*PPARγ*).** A polymorphism (Pro115Gln) in this gene was found to be associated with adipocyte differentiation and greater cellular accumulation of triglyceride (278). Another polymorphism (Ala allele of Pro12Ala polymorphism) was associated with lower BMI, increased insulin sensitivity and higher plasma HDL levels (363). Associations of these and other (*PPARγ*) polymorphisms with obesity and other metabolic syndrome phenotypes were replicated in several populations (364,365), but explained only a tiny fraction of the inherited risk of obesity.

**90.3.3.1.4 Beta 2- and Beta 3-Adrenergic Receptor Genes (*ADRB2*, *ADRB3*).** As described in Section 90.2.2.1, polymorphisms in this adrenergic receptor gene were associated with BMI and fasting fatty acid levels in some populations in linkage and candidate gene studies (366,367). The beta 2- and beta 3-adrenergic receptor genes were also implicated in onset of obesity as well as blood pressure elevation in other studies (368) but these associations have not replicated in all studies (369,370). Some evidence suggests an additive effect of the Beta 3 adrenergic gene and UCP-1 gene variants on body-size phenotypes (371,372).

**90.3.3.1.5 *MC4R*.** The melanocortin 4 receptor is an integral component of the leptin-melanocortin

TABLE 90-5

Chromosomal Location	Suspected Gene(s)	Function	Reference
1p31	NEGR1(Neural growth regulator 1)	Axonal growth promoter	(425)

16q22.2	FTO	Nucleic acid demethylase; other functions?	(357) Multiple others
18q11.2	NPC1	Niemann–Pick disease gene; intracellular cholesterol trafficking	(428)
18q22	MC4R	Melanocortin 4 receptor, appetite regulation. Associated with monogenic obesity	(430) Multiple others
19q13.11	KCTD15	Potassium channel	(425,427)

Human genetic loci associated with GWAS or epigenetics studies. Based on Reference (375), Figure 90-1.

regulatory pathway and disruptions in this receptor are the most common monogenic cause of severe obesity. GWAS scans reveal that polymorphisms in and around this gene are also associated with BMI in diverse populations (373,374). It is likely that variations in the functionality of this receptor lead to alterations in satiety and a change in body weight because of increased appetite.

**90.3.3.1.6 UCP Genes.** UCPs are mitochondrial proteins that help to dissipate the proton gradient at the inner mitochondrial membrane, decreasing the generation of ATP. It has been postulated that polymorphisms in the various uncoupling proteins (UCP1, 2 and 3) can lead to alteration in energy expenditure and thus in the accumulation of fat. Members of this gene family were initially implicated in obesity using candidate gene approaches (177) and these associations have been replicated in several populations.

**90.3.3.1.7 Others.** Other genes including TNF $\alpha$  gene (TNFA), angiotensin-converting enzyme gene (ACE), G-protein beta3 subunit gene (GNB3), leptin gene (LEP), leptin receptor (LEPR), SLC6A14, GAD2, TMEM18, INSIG2 and ENPP1 have been linked to the risk of obesity in different studies (375,376). Their exact role remains unclear in many cases and their combined contribution to the obesity epidemic is relatively small. Many examples of human loci identified in GWAS and

imprinting or epigenetics studies as correlated with body size variables are listed in Table 90-5.

### 90.3.3.2 Addressing the Human Obesity Problem: Predictive Factors, Prevention Strategies, and Treatments.

**90.3.3.2.1 Prediction of Adult Obesity during Childhood.** It is well known that blood pressure, blood lipid levels, and obesity in childhood tracks into adulthood (377). Thus childhood obesity itself is a predictor of adult obesity (378), and of higher-than-expected adult morbidity and mortality (379). These late effects may be unrelated to the presence of overweight in adulthood (380). The presence of a specific growth pattern termed early adiposity rebound may predict adult obesity in young children (381). Early adiposity rebound is associated with parental obesity but not with socioeconomic status or dietary variables (382). Whereas most of the comorbidities of obesity occur in adults, they are definitely present in youth in their presymptomatic or early symptomatic forms (38,42,383,384), and when present in children, they are associated with increased cardiovascular morbidity and mortality in their relatives (38–40). The prevalence of clinically significant obesity-related morbidities in youth is definitely on the rise (385), and predicts earlier onset of more severe problems in adolescents, especially among African-Americans (386), and in young adults (387). The alarming increase in type 2 diabetes among

children and adolescents is directly related to the obesity epidemic (388).

Many investigators have established the importance of parental obesity as a predictive factor for childhood obesity. In a study of the influence of different aspects of the home environment on obesity in nearly 3000 children <8 years of age, maternal obesity was the most significant predictor of childhood obesity (389). High birth weight is a significant predictor of later obesity, and the most important factor contributing to high birth weight is maternal diabetes and, to a lesser degree, maternal obesity (390). The relative risk of developing obesity in young adulthood is higher for young children if they have obese parents, and higher for older children if they themselves are obese (391) (Table 90-6).

The influence of lack of physical activity on the development of obesity is reflected in the NHANES data, especially from the most recent survey. Lack of physical activity is directly related to television viewing, and hours of television are significantly correlated to weight gain during the growing years (392). Reduction in television viewing significantly reduced the rate of weight gain in a study of third-grade children, when compared to third graders with no intervention (393).

**90.3.3.2.2 Prevention Strategies.** Obviously, community-wide efforts need to be directed toward increasing physical activity, and changing dietary habits. Reduction of dietary calories and fat, and increasing dietary fiber are recommended (394). The CDC has developed a resource guide for prevention of obesity and other chronic diseases that cover many aspects of nutrition, physical activity, and other lifestyle interventions (395). Counseling obese parents about the risk of childhood obesity in their children must be practiced by health care providers. Enhancement of physical education programs must be instituted by the school systems. It has been established that breast-fed infants are less likely to develop adult obesity than bottle-fed infants (396), adding obesity prevention to the list of benefits of breast feeding, which health care providers should convey.

**90.3.3.2.3 Treatments.** Despite the identification of specific single gene defects and metabolic abnormalities

resulting in obesity, novel efficacious therapeutic interventions have not been forthcoming.

**90.3.3.2.4 Medications.** Current medical therapeutic options for treatment of obesity are not very promising, and the principals of therapy are flawed. Therapy must be long-term and ongoing, as is the case with treatment of hypertension and diabetes. Current obesity drugs are not approved for prolonged use, or for use in youth, have not been extensively tested for safety over long periods of time, may only benefit a minority of patients (12,397), and are associated with serious cardiovascular side effects (398). The latter has resulted in two such agents being taken off the market. The major classes of drugs are those that reduce food intake (monoamine oxidase inhibitors, sympathomimetic drugs), those that increase energy expenditure (ephedrine, caffeine), and those that inhibit fat absorption. The use of agents to induce dietary fat malabsorption has been only minimally successful, and is associated with significant intestinal discomfort if not accompanied by a low-fat diet. Of course, the diet itself may be nearly equally effective over the long-term.

The use of recombinant leptin in humans resulted in a modest and highly variable loss of weight (loss of fat mass), which was dose related, and occurred in both lean and obese subjects (399). Leptin treatment in the rare leptin-deficient patients produced a rapid reduction in weight and increase in energy expenditure, and antibodies to leptin developed after 2 months (400).

In an animal study, mice that were treated with fatty acid synthase inhibitors had a reduction in food intake and in body weight (401). This treatment was effective when given either systemically or intracerebroventricularly. It inhibited NPY expression in the hypothalamus, as well as leptin expression in WAT.

**90.3.3.2.5 Surgery.** Bariatric surgery perhaps provides the best weight loss results (402), but both short- and long-term risks are present. Bariatric surgical procedures fall into two categories—those reducing gastric volume, such as vertical banded gastroplasty or adjustable gastric band, and those that also result in moderate selective malabsorption such as gastric bypass. Bypass results in more rapid and more significant weight loss. As a result, there is a recent trend toward gastric bypass as the preferred procedure. However, there is an altered gut hormone response to feeding, potential for deficiencies of vitamin B12, folate, and iron leading to anemia, as well as secondary hyperparathyroidism, presumably due to reduction of calcium absorption due to loss of gastric acidity. Vertical banded gastroplasty has been associated with loss of bone density without hyperparathyroidism (403). Several studies confirmed that gastric bypass results in reduction in diabetes and hypertension (404,405), but the risk for metabolic bone disease, vitamin deficiencies, and intestinal complications is high (406–409). Surgery to remove fat (liposuction), if used alone, is not a long-term solution. However, it may

**TABLE 90-6 Odds Ratios for Obesity in Young Adulthood According to Obesity Status in Childhood and Parents' Obesity Status**

Age (yr)	Obese as Child Yes versus No	Number of Obese Parents	
		1 versus 0	2 versus 0
1–2	1.3	3.2	13.6
3–5	4.7	3.0	15.3
6–9	8.8	2.6	5.0
10–14	22.3	2.2	2.0
15–17	17.5	2.2	5.6

Data were obtained with permission from Reference (391).

be a useful cosmetic adjunct in patients who are successful with diet and exercise, or surgical gastroplasty.

### 90.3.3.2.6 Future Directions in Treatment.

Of course, the most significant impact on the obesity epidemic will have to be achieved through patient education and prevention strategies. Many resources offering guidance in these areas are available (410) (see also [www.cdc.gov](http://www.cdc.gov) and [www.surgeongeneral.gov](http://www.surgeongeneral.gov)). New medical treatments, including potent agonists for the  $\beta$ 3-AR and the MC4R, are under development. Presymptomatic genotyping using microarray technologies may be able to identify those individuals genetically predisposed to obesity, allowing prevention strategies to be initiated early. Gene or hormone replacement therapy may become available for those rare patients with single gene defects. Direct electrostimulation of specific hypothalamic nuclei has been successful in increasing metabolic rate and fat utilization, and decreasing feeding in rats (411). Similar techniques are used in humans to treat tremors, and perhaps could be applied to obesity treatment.

### Biographies

**Patricia A Donohoue** attended medical school at The Ohio State University, and completed her internship in Pediatrics there at what is now known as Nationwide Children's Hospital. She completed her second and third years of pediatric residency at Rainbow Babies and Children's Hospital, Case Western Reserve University. Her Pediatric Endocrinology Fellowship was at Johns Hopkins under the mentorship of Professor Claude Migeon and the late Professor Neil Van Dop. She stayed there as a junior faculty member for 4 years before moving to the University of Iowa. At Iowa, she continued her NIH-funded laboratory research on the genetics of steroid 21-hydroxylase deficiency, and then focused her interest on other inherited defects of the hypothalamic–pituitary–adrenal axis, and eventually on the genetics of obesity. After 18 years at the University of Iowa, she moved to the Medical College of Wisconsin in Milwaukee in 2008, where she is a Professor of Pediatrics and Section Chief of Pediatric Endocrinology and Diabetes.

**Omar Ali, MD** attended medical school at King Edward Medical College in Lahore, Pakistan, and completed his residency in pediatrics at Jersey City Medical Center. He then did a 1-year fellowship in community pediatrics at the Children's Hospital of Pittsburgh. He worked in general pediatrics for the next 12 years, but then decided to do a fellowship in Pediatric Endocrinology at UCLA-Mattel Children's Hospital under Dr Hassy Cohen. Subsequently, he joined the Medical College of Wisconsin in 2006. He is an Assistant Professor of Pediatrics in the Section of Pediatric Endocrinology and Diabetes, and Director of the Pediatric Endocrinology Fellowship Program. His research interest is the genetics and epigenetics of obesity and the metabolic syndrome, and he is currently working on grants funded by the NIH, the National Children's study and the Children's Research Institute.

## Genetic Lipodystrophies

*Abhimanyu Garg*

Division of Nutrition and Metabolic Diseases, Department of Internal Medicine,  
Center for Human Nutrition, UT Southwestern Medical Center at Dallas,  
Dallas, TX, USA

### 91.1 INTRODUCTION

Lipodystrophies are disorders of adipose tissue characterized by selective loss of body fat and a predisposition to develop insulin resistance and its complications (1). The prevalence of metabolic and other manifestations of insulin resistance, such as impaired glucose tolerance, diabetes, hyperinsulinemia, dyslipidemia, hepatic steatosis, acanthosis nigricans, polycystic ovarian disease and hypertension, varies among the different subtypes of lipodystrophies and is generally determined by the extent of adipose tissue loss (1). The loss of adipose tissue is readily apparent in females, and thus the diagnosis of lipodystrophies is relatively easy in them but it may be missed in affected males as many normal men look muscular and have much less body fat than women. Lipodystrophies can be classified into genetic syndromes and acquired disorders due to various causes (1,2). The inherited lipodystrophy syndromes can be subclassified into autosomal-recessive or autosomal-dominant disorders and a classification is given in Table 91-1 (2). The precise mode of inheritance still remains to be characterized for some disorders.

A great deal of progress has been made recently in elucidating the genetic basis of many types of inherited lipodystrophies (1,2); however, the defective genes for some disorders still remain to be discovered. The discoveries of the molecular mechanisms underlying various types of genetic lipodystrophies has added to our understanding of adipocyte biology and has revealed potential pathways, which may be implicated in development of insulin resistance in these disorders as well as in other common disorders of adipose tissue such as generalized and regional obesity (3).

### 91.2 MECHANISMS OF INSULIN RESISTANCE AND ITS COMPLICATIONS IN LIPODYSTROPHIES

The underlying mechanisms causing insulin resistance in patients with lipodystrophies may be similar to those implicated in obesity. For example, in patients with

severe forms of obesity and lipodystrophies, there may be limitation in further storage of triglycerides in adipose tissue resulting in diversion of dietary and endogenously synthesized triglycerides to aberrant sites, such as the liver and skeletal muscles resulting in insulin resistance (4). The frequency of hepatic steatosis differs in patients with various lipodystrophies. For example, nearly all patients with congenital generalized lipodystrophy (CGL) have some degree of hepatic steatosis since birth whereas only a few patients with familial partial lipodystrophies (FPL) may develop hepatic steatosis (5,6). Accumulation of triglycerides in skeletal muscle has not been studied systematically. Slight increase in skeletal muscle triglyceride was noted even in patients with CGL (7). The ectopic triglyceride accumulation may induce hepatic and skeletal muscle insulin resistance; however, the precise molecular mechanisms by which this occurs have not been elucidated. Hypertriglyceridemia and lowering of high-density lipoprotein (HDL) cholesterol in patients may be related to severity of hepatic steatosis. Clinically, a dramatic reduction in insulin resistance as well as hepatic steatosis is observed when patients reduce energy intake because of either exogenous leptin therapy or otherwise (8,9).

The mechanisms of diabetes mellitus seem to be similar to that noted in patients with type 2 diabetes. Marked islet amyloidosis and pancreatic  $\beta$  cell atrophy was observed on autopsy of two lipodystrophic patients with diabetes, one with CGL and another with Familial Partial Lipodystrophy, Dunnigan variety (FPLD) (6,10). Diabetes in patients with lipodystrophies is usually ketosis resistant and many patients require extremely high doses of insulin to achieve good glycemic control (8). Whether the resistance to ketosis is due to residual endogenous insulin secretion or due to reduced flux of free fatty acids, the substrates for production of ketones, is not clear.

Extremely high serum levels of insulin may be implicated in other clinical manifestations noted in patients with lipodystrophies such as acanthosis nigricans, acromegaly features (enlargement of mandible, hands

**TABLE 91-1 Classification of Genetic Lipodystrophies**

<b>A. Autosomal-Recessive Syndromes</b>	
1.	Congenital generalized lipodystrophy (CGL; Berardinelli–Seip Syndrome)
a.	CGL Type 1: <i>AGPAT2</i> (1-acylglycerol-3-phosphate O-acyltransferase 2) mutations
b.	CGL Type 2: <i>BSCL2</i> (Berardinelli–Seip congenital lipodystrophy 2) mutations
c.	CGL Type 3: <i>CAV1</i> (Caveolin 1) mutation
d.	CGL Type 4: <i>PTRF</i> (polymerase I and transcript release factor) mutations
e.	Other varieties
2.	Mandibuloacral dysplasia (MAD)-associated lipodystrophy
a.	Partial lipodystrophy (Type A pattern): <i>LMNA</i> (lamin A/C) mutations
b.	Generalized lipodystrophy (Type B pattern) <i>ZMPSTE24</i> (zinc metalloproteinase) mutations
c.	Other varieties: Unknown
3.	Autoinflammatory syndromes
a.	JMP syndrome: <i>PSMB8</i> (proteasome subunit, beta-type, 8) mutations;
b.	CANDLE syndrome: <i>PSMB8</i> mutations
4.	Familial Partial Lipodystrophy (FPL): <i>CIDEA</i> (cell death-inducing DNA fragmentation factor a-like effector c) mutation
5.	SHORT (Short stature, Hyperextensibility or inguinal hernia, Ocular depression, Rieger anomaly and Teething delay) syndrome: Unknown
6.	Mandibular hypoplasia, Deafness, Progeroid features (MDP)-associated lipodystrophy: Unknown
7.	Neonatal Progeroid (Weidemann–Rautenstrauch) Syndrome: Unknown
<b>B. Autosomal-Dominant Syndromes</b>	
1.	Familial Partial Lipodystrophy (FPL)
a.	FPL, type 1, Kobblerling variety: Unknown
b.	FPL, type 2, Dunnigan variety (FPLD): <i>LMNA</i> (lamin A/C) mutations
c.	FPL type 3: <i>PPARG</i> (peroxisome proliferator-activated receptor- $\gamma$ ) mutations
d.	FPL type 4: <i>AKT2</i> (v-AKT murine thymoma oncogene homolog 2) mutation
e.	FPL, type 5: <i>PLIN1</i> (perilipin 1) mutations
f.	Other varieties: Unknown
2.	Atypical progeroid syndrome: <i>LMNA</i> mutations
3.	Hutchinson–Gilford progeria syndrome: <i>LMNA</i> mutations
4.	SHORT syndrome: Unknown

and feet), generalized organomegaly and clitoromegaly as well as polycystic ovarian disease. These may occur because of “specificity spillover phenomenon” and actions of high levels of insulin through other receptors such as those for insulin-like growth factors, I and II. The precise molecular mechanisms involved in various clinical manifestations are expected to be revealed in the near future as we make progress in understanding biological processes related to the genes implicated in causing genetic lipodystrophies.

### 91.3 GENETIC LIPODYSTROPHIES

Most of the patients with genetic lipodystrophies reveal a classical autosomal-recessive (congenital generalized or mandibuloacral dysplasia (MAD)-associated) or autosomal-dominant inheritance pattern (FPL). However, for the SHORT-syndrome-associated lipodystrophy, both autosomal-recessive and autosomal-dominant inheritance patterns have been reported. In the following section, each type of inherited lipodystrophy is discussed.

#### 91.3.1 Autosomal-Recessive Types

**91.3.1.1 Congenital Generalized Lipodystrophy (Berardinelli–Seip Syndrome).** This autosomal-recessive disorder (Online Mendelian Inheritance in Man #269700)

was reported originally by Berardinelli from Brazil approximately 57 years ago (11). Shortly thereafter, Seip from Norway provided detailed description of the phenotype (12). The diagnosis of CGL is made usually at birth or shortly thereafter. Approximately 300 cases have been reported from all over the world. It is more commonly reported from the racial and ethnic groups such as from Brazil and Lebanon, where consanguinity is common (13,14). If the reported cases represent only one-fourth of the actual cases, the estimated prevalence of this disorder is about 1 in 10 million.

**91.3.1.1.1 Clinical and Biochemical Characteristics.** The affected newborns appear “strikingly muscular” because of almost complete absence of adipose tissue. They grow at an accelerated rate and their bone age may be advanced. Children display markedly increased appetite. Slight enlargement of the hands, feet and mandible (“acromegaloid” features) are apparent (Figure 91-1A). Umbilical hernia or enlargement of the umbilicus is observed commonly. Acanthosis nigricans usually develops late in the childhood or adolescence and may affect extensive area of the body such as the trunk, hands, elbows, knees and ankles besides the common sites at the neck, axillae and groins.

Hepatomegaly is usually noticed during infancy and is due to hepatic steatosis. A few patients develop cirrhosis and its complications later on in life. Many patients

**(A)** **(B)**  
**FIGURE 91-1** CGL. Panels A and B show anterior and posterior views, respectively, of a 37-year-old female of African-American origin with congenital generalized lipodystrophy type 1, showing generalized lack of fat, extreme muscularity and acromegaly features. She developed diabetes mellitus at the age of 17 years. Acanthosis nigricans was present in the neck, axillae and groin. She had a homozygous mutation (IVS4-2A>G resulting in prematurely truncated protein Gln196fsX228) in the *AGPAT2* gene.

develop splenomegaly. In postpubertal females, mild hirsutism, clitoromegaly, oligoamenorrhea and polycystic ovaries are common. Most affected women are unable to get pregnant but successful pregnancy has been reported. Affected men usually have normal reproductive ability. Many patients develop focal lytic lesions in the appendicular bones after puberty, commonly involving the humeri, but also sometimes affecting the femur, radius, ulna, carpal, tarsal and phalangeal bones (15). These lytic lesions may be related to the lack of bone marrow fat and inability to replace hematopoietic marrow with adipose tissue during childhood and adolescence. Hypertrophic cardiomyopathy and mild mental retardation have been reported in some patients (16–19).

Patients have marked fasting and postprandial hyperinsulinemia suggestive of severe insulin resistance. Extreme hypertriglyceridemia predisposes patients to recurrent episodes of acute pancreatitis. Levels of HDL cholesterol also tend to be low. Diabetes is usually noted during the pubertal years; however, the onset of diabetes

has occurred as early as 6 weeks of life (18). In some neonates, diabetes occurs transiently during period of stress or infection only to recur later in life. Patients require high doses of insulin to control diabetes.

Consistent with the near total absence of body fat, the serum levels of adipocytokines, such as leptin and adiponectin, are low (20). It is likely that hypoleptinemia contributes to excessive appetite and metabolic complications in patients with CGL.

#### 91.3.1.1.2 Genetic Defect and Pathophysiology.

Using genome-wide linkage analysis, we reported the first locus for CGL on human chromosome 9q34 (21) and described genetic heterogeneity in 17 pedigrees. Subsequently, another locus was found on chromosome 11q13 (13). Positional cloning approach led us to identify mutations in the 1-acylglycerol-3-phosphate-O-acyltransferase 2 (*AGPAT2*) gene in affected patients from pedigrees linked to 9q34 (17). The defective gene on chromosome 11q13 was found to be a novel gene, called Berardinelli-Seip Congenital Lipodystrophy 2 (*BSCL2*) and the product of the gene was named Seipin, after Seip (13). Recently, candidate gene approach has led to the identification of two additional CGL loci, caveolin 1 (*CAV1*) (22) and polymerase I and transcript release factor (*PTRF*) (23).

The *AGPAT*s belong to the acyltransferase family of enzymes and 11 isoforms, each encoded by a different gene are known currently (24–26). The *AGPAT*s catalyze an important step in the biosynthesis of glycerophospholipids and triglycerides. These enzymes acylate lysophosphatidic acid (1-acylglycerol-3-phosphate) to phosphatidic acid (1,2 diacylglycerol-3-phosphate) (24,27) (Figure 91-2). Each isoform may have substrate specificity for different fatty acids but precise nature of it remains unclear. These isoforms may also differ in subcellular localization and may play different roles in mitochondrial or microsomal synthesis of triglyceride or phospholipids. There may also be heterogeneity as far as expression of these isoforms in various tissues, particularly among adipose tissue depots localized at different regions of the body.

Of the two major isoforms of *AGPAT*, 1 and 2, we reported that *AGPAT2* is highly expressed in the omental adipose tissue (17), but *AGPAT1* showed an equal expression in the liver and its expression was nearly twofold in the skeletal muscle. Thus, it can be hypothesized that mutations of *AGPAT2* gene may cause lipodystrophy either by reducing triglyceride deposition in the adipocytes or by affecting adipocyte function resulting from the lack of synthesis of phospholipids. *AGPAT2* consists of 278 amino acids and shares two highly conserved motifs, Asn-His-x-x-x-Asp (amino acids 97–103, with x denoting any amino acid) and Glu-Gly-Thr-Arg (amino acids 172–175) with other acyltransferases. These motifs are critical for the enzymatic activity (24,28). Besides the well-conserved motifs, we have recently reported that carboxy-terminal residues are also important determinants of the *AGPAT2* enzymatic

activity (29). Using *in vitro* expression of wild-type and mutant forms of AGPAT2 in Chinese Hamster Ovary cells, we found that null mutants had markedly reduced activity to convert lysophosphatidic acid to phosphatidic acid and the missense mutants had mild to moderate reduction in activity (29). However, because of reduced sample size, compound heterozygous mutations in many patients, and the fact that most of the CGL patients do present with near-total absence of body fat, we were unable to find a genotype–phenotype relationship.

The *BSCL2* encodes a 398-amino-acid transmembrane protein, seipin, which does not reveal any striking homology to any other protein. It contains a CAAX motif at the C-terminal and a glycosylation site, Asn-Val-Ser, at position 88–90. We previously reported a weak but not insignificant homology of seipin to the linker region of the protein called midasin (30). Interestingly, missense mutations in the glycosylation motif of seipin have been reported to cause distal hereditary motor neuropathy and Silver syndrome most likely by aggresome formation (31). Recent data suggest the role of seipin in lipid droplet formation and in adipocyte differentiation (32–34).

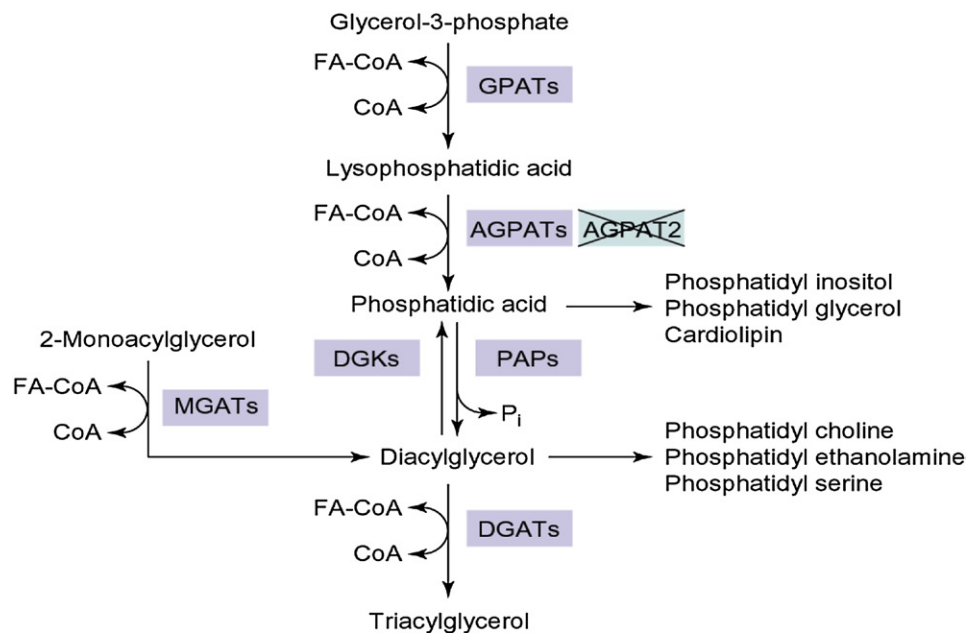

Caveolin 1 is expressed in caveolae, which are specialized microdomains on cell membranes of adipocytes (35). It contributes to lipid droplet formation by binding

fatty acids and translocating those to lipid droplets. PTRF is also known as cavin, and plays a role in biogenesis of caveolae. PTRF regulates expression of caveolins 1 and 3 (23).

#### 91.3.1.1.3 Genotype and Phenotype Variation.

There are phenotypic differences in the two most prevalent types of CGL, called type 1 (*AGPAT2* related) and type 2 (*BSCL2* related) (17–19). Patients with CGL, type 2 have increased prevalence of cardiomyopathy and mild mental retardation (17–19), while focal lytic lesions in appendicular skeleton are more prevalent in CGL type 1 (36). In both the types, metabolically active adipose tissue, which is found in most subcutaneous (sc) areas, intra-abdominal and intrathoracic regions, and bone marrow, is nearly completely lost (36). The mechanical adipose tissue depots located in the palms, soles, under the scalp, retro-orbital and periarticular regions are spared in CGL, type 1 but severe loss of fat also occurs from these depots in patients with CGL, type 2 (5,36,37). Serum leptin levels also tend to be lower among those with type 2 CGL compared to those with type 1 CGL but interestingly, they have increased serum adiponectin levels (18).

CGL, type 3 has been reported in only one Brazilian girl who had a homozygous *CAVI* mutation and had

TRENDS in Endocrinology & Metabolism

**FIGURE 91-2** Pathways for biosynthesis of triacylglycerol: glycerol-3-phosphate (G3P) is the initial substrate for acylation at sn-1 position by the enzyme glycerol-3-phosphate acyltransferase (GPAT), to form 1-acylglycerol-3-phosphate or lysophosphatidic acid (LPA). LPA is further acylated at sn-2 position by 1-acylglycerol-3-phosphate acyltransferase (AGPAT, aka LPAAT) to form phosphatidic acid (PA). In the next step, phosphate group is removed by phosphatidate phosphohydrolase (PAP) to produce diacylglycerol (DAG). DAG is further acylated at sn-3 position by diacylglycerol acyltransferase (DGAT) to produce triacylglycerol (TG). In addition, TG can be synthesized via the acylation of 2-monoacylglycerol by the enzyme monoacylglycerol acyltransferase (MGAT), which is highly expressed in small intestine. DAG kinase (DGK) can phosphorylate DAG to synthesize PA. PA and DAG are also substrates for the synthesis of glycerophospholipids such as phosphatidylinositol (PI), cardiolipin, phosphatidylcholine (PC), phosphatidylethanolamine (PE) and phosphatidylserine (PS). (Reproduced with permission from Elsevier. Agarwal, A. K.; Garg, A. *Congenital Generalized Lipodystrophy: Significance of Triglyceride Biosynthetic Pathways*. Trends Endocrinol. Metab. 2003, 14 (5), 214–221.)

short stature and presumed Vitamin D resistance (22). Type 4 CGL due to *PTRF* mutations has been reported in approximately 21 patients. Peculiar finding in these patients include congenital myopathy, percussion-induced myoedema, pyloric stenosis and atlantoaxial instability. Of particular concern are arrhythmias including prolonged QT interval and exercise-induced ventricular tachycardia, and sudden death (23,38,39). Patients with *CAV1* and *PTRF* mutations have well-preserved mechanical and bone marrow fat (22,36,38,40). There are a few patients with CGL who do not have mutations in the four known loci and may lead us to yet more novel loci.

In our experience as well as of that of others, nearly all patients of African origin harbor the founder mutation (IVS4-2A>G) in *AGPAT2*, whereas patients of Lebanese origin have a founder mutation (659delGTATC) in *BSCL2* (18) (Figures 91-3 and 91-4). Patients of European and Asian descent have been reported to harbor mutations in either of the two genes. CGL, type 3 has been reported from Oman in several pedigrees.

#### 91.3.1.1.4 Molecular and Differential Diagnosis.

Patients with CGL can be easily diagnosed at birth or

immediately thereafter. The two main types of CGL can be distinguished based on their clinical features. Diagnosis at the molecular level may be needed in some but it raises economic and ethical issues. Couples with a child affected with CGL may use molecular diagnosis to know their risk of having another child with CGL. Finally, molecular diagnosis can be used for prenatal screening.

Many different syndromes can present phenotype similar to CGL such as acquired generalized lipodystrophy with onset during early infancy, leprechaunism, atypical Werner syndrome, pubertal-onset generalized lipodystrophy due to rare *LMNA* mutations and neonatal progeroid syndrome.

**91.3.1.2 Mandibulo-Acral Dysplasia (MAD)-Associated Lipodystrophy.** MAD (OMIM #248370) is a rare autosomal-recessive disorder characterized by hypoplasia of the mandible and clavicles, and acro-osteolysis (resorption of the terminal phalanges) (41,42). Patients also have delayed closure of cranial sutures, joint contractures, mottled cutaneous pigmentation and short stature. Features of accelerated aging called “progeroid features” such as bird-like facies, high-pitched voice and

I.; Garg, A. *Genetic Basis of Congenital Generalized Lipodystrophy*. *Int. J. Obesity* 2004, 28, 336–339.)

**FIGURE 91-5** MAD. A. Lateral view of a 20-year-old Hispanic female with MAD due to homozygous Arg527His missense mutation of the *LMNA* gene. She had reconstructive surgery for micrognathia. She had loss of fat from the extremities leading to a muscular appearance and prominent subcutaneous veins and had excess fat accumulation in the face and neck region. Note the mottled skin pigmentation over the trunk. B. Hands show rounding of the finger tips and clubbing appearance due to acro-osteolysis of the terminal phalanges. There is atrophy of the skin on the dorsum of hands especially over the interphalangeal joints and metacarpophalangeal joints.

ectodermal defects, such as skin atrophy, pigmentation, alopecia, and nail dysplasia are also seen in some patients. Only a few patients have had hypogonadism and sensorineural deafness. Approximately 40 patients with MAD have been reported in the literature (Figure 91-5).

Patients with MAD display two patterns of lipodystrophy: type A pattern with partial loss of sc fat from the extremities and type B pattern with more generalized loss of sc fat involving the face, trunk and extremities (41). Hyperinsulinemia, insulin resistance, impaired glucose tolerance, diabetes mellitus and hyperlipidemia have been reported but are usually mild to moderate in severity (41).

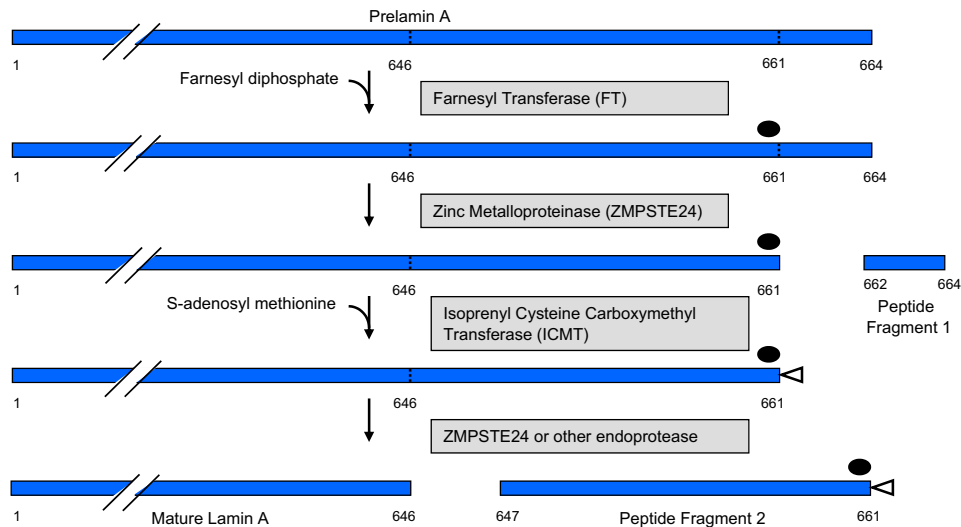

**91.3.1.2.1 MAD-Associated Partial Lipodystrophy due to *LMNA* Mutations.** Novelli et al. (42) reported a homozygous Arg527His mutation in *LMNA* gene in MAD patients with type A (partial) lipodystrophy of Italian origin. The heterozygotes had no phenotypic manifestations of MAD. *LMNA* encodes lamins A and C by alternative splicing in exon 10 (43). Prelamin A has a CAAX motif at its C-terminal, which undergoes posttranslational modification involving an endoprotease called *zinc metalloproteinase* (ZMPSTE24) to form

mature lamin A (Figure 91-6). The lamins belong to the intermediate filament family of structural proteins. Lamins A and C form hetero- or homodimeric coiled-coil structures and are integral components of the nuclear lamina; a polymeric structure intercalated between chromatin and the inner membrane of the nuclear envelope (44,45). The mechanisms by which this *LMNA* mutation causes predominantly skeletal and cutaneous dystrophy but less-severe lipodystrophy in patients with MAD, remain unclear. By now, a total of 30 patients with MAD due to various *LMNA* mutations have been reported (41,42, 46–48). Some patients have more-severe progeroid manifestations, such as those seen in Hutchinson–Gilford progeria syndrome (HGPS) such as alopecia, loss of eyebrows, delayed sexual maturation and premature loss of teeth. Most of the *LMNA* mutations causing MAD are located in the C-terminal region affecting exons 8–10. How these specific *LMNA* mutations cause resorption of bones such as mandible, clavicles and terminal phalanges remains unclear.

**91.3.1.2.2 MAD-Associated Generalized Lipodystrophy due to Zinc Metalloproteinase (*ZMPSTE24*) Mutations.** On the basis of the critical role of ZMPSTE24 in posttranslational maturation of prelamin A to its mature form lamin A and the phenotype of lipodystrophy and skeletal abnormalities in ZMPSTE24-deficient mice (49,50), we sequenced *ZMPSTE24* gene in MAD patients who did not have mutations in *LMNA* gene. We found compound heterozygous mutations in the *ZMPSTE24* gene in a Belgian woman with MAD (51). She also had progeroid features and generalized lipodystrophy (51). She died prematurely at age 24 years of complications of chronic renal failure due to collapsing variety of focal segmental glomerulosclerosis (51). Given the role of ZMPSTE24 in posttranslational proteolytic processing of prelamin A, cellular accumulation of prelamin A and/or lack of mature lamin A may be responsible for phenotypic features (52). A recent study suggests toxic effects of prelamin A accumulation to be responsible for the phenotype in ZMPSTE24-deficient mice (53). In our cohort of patients with MAD, some patients do not have any variants in either *LMNA* or *ZMPSTE24* genes, suggesting additional as yet unmapped loci (51).

**91.3.1.2.3 Genotype and Phenotype Variation.** About 30 patients have been reported to have MAD due to *LMNA* mutations, but only eight MAD patients have *ZMPSTE24* mutations. Several MAD patients have been reported from Italy and all of them have a founder *LMNA* Arg527His mutation (42). MAD patients with *LMNA* or *ZMPSTE24* mutations share features of mandibular and clavicular hypoplasia and acro-osteolysis but patients with *ZMPSTE24* mutations are premature at birth, have early onset of skeletal defects including acro-osteolysis, have more progeroid appearance and develop sc calcified nodules on the phalanges. We have reported focal segmental glomerulosclerosis in two

**FIGURE 91-6** Posttranslational processing of prelamins A and B. Prelamin A contains 664 amino acids and a conserved CAAX motif at the carboxy terminal. The cysteine residue in the CAAX motif is first farnesylated by the farnesyl transferase (shown by filled circles) followed by first proteolytic cleavage of the three extreme C-terminal residues by zinc metalloproteinase (ZMPSTE24). Then, the farnesylated cysteine residue is methylated by isoprenylcysteine carboxyl methyl transferase (ICMT) using S-adenosyl methionine as the methyl donor (shown by unfilled triangle). Thereafter, ZMPSTE24 or other endoprotease cleave the 15 amino acids from the C-terminal forming the mature lamin A with 646 residues. (Reproduced with permission from Elsevier Inc. Garg, A.; Misra, A. *Lipodystrophies: Rare Disorders Causing Metabolic Syndrome*. Endocrinol. Metab. Clin. North Am. 2004, 33, 305–331.)

patients with ZMPSTE24 deficiency; kidney pathology has not been reported in those with *LMNA* mutations (51). Interestingly, the remaining patients, who do not harbor *LMNA* or ZMPSTE24 variants, do not seem to develop clavicular resorption or acro-osteolysis.

#### 91.3.1.2.4 Molecular and Differential Diagnosis.

Ascertaining molecular diagnosis may help predict peculiar clinical features noted in different genetic varieties of MAD. Patients with MAD have several overlapping clinical features with HGPS and those with atypical Werner syndrome (all due to heterozygous mutations in *LMNA*) and should be differentiated from such patients. Patients with several other genetic syndromes, such as, Hajdu-Cheney, congenital insensitivity to pain with anhidrosis, Haim-Munk, and Papillon-Lefevre syndromes present with acro-osteolysis as well and need to be differentiated from patients with MAD.

#### 91.3.1.3 Autoinflammatory Syndromes.

**91.3.1.3.1 Joint Contractures, Muscle Atrophy, Microcytic Anemia and Panniculitis-Induced (JMP) Lipodystrophy.** Recently, an autosomal-recessive, auto-inflammatory, JMP syndrome was reported by us in a patient from Portugal and two siblings from Mexico (54). These patients started developing progressive panniculitis-induced lipodystrophy during childhood. Previously, three patients with very similar features were reported from Japan (55,56). Other reported features of JMP syndrome include intermittent fever, hypergammaglobulinemia, elevated erythrocyte sedimentation rate, hepatosplenomegaly and calcification of basal ganglia (Figure 91-7).

Genome-wide linkage analysis was conducted by us in the two pedigrees with JMP syndrome and we looked for regions of extended homozygosity in the affected

patients. These studies linked JMP syndrome to chromosome 6. Sequencing of immune response genes in this region led us to a homozygous, missense (Thr75Met) loss of function, mutation in proteasome subunit, beta-type, 8 (*PSMB8*) gene in affected patients from both the pedigrees (57). *PSMB8* encodes the  $\beta 5i$  subunit of the immunoproteasome (58). Immunoproteasomes are responsible for proteolysis of antigens presented by major histocompatibility complex class I molecules and result in generation of immunogenic epitopes. We believe that the mutation in *PSMB8* may trigger autoinflammatory response which results in panniculitis and other autoinflammatory manifestations. Two other groups from Japan have recently confirmed our findings and have reported another missense mutation, Gly201Val, in *PSMB8* in patients with autoinflammation and lipodystrophy (59,60).

**91.3.1.3.2 Chronic Atypical Neutrophilic Dermatitis with Lipodystrophy and Elevated Temperature (CANDLE) Syndrome.** This is a relatively new syndrome reported by two groups in a total of five patients. Clinical manifestations include onset of recurrent fever and annular violaceous plaques during infancy which result in loss of sc fat from the face and upper limbs (61,62). Patients develop violaceous swelling of the eyelids, hepatosplenomegaly, arthralgias, hypochromic anemia, raised erythrocyte sedimentation rate and basal ganglia calcifications. On the basis of limited data, the mode of transmission seems to be autosomal recessive. Recently, homozygous Cys135X and Thr75Met mutations in *PSMB8* have been reported in patients with CANDLE syndrome (63).

**91.3.1.4 Familial Partial Lipodystrophy (FPL) due to CIDEC Mutation.** A single patient with

**FIGURE 91-7** JMP syndrome. A. 26-year-old Hispanic female with more marked loss of sc fat from the face, neck, chest and upper extremities than from the abdomen, hips and lower extremities, which were spared. The breasts were atrophic and the neck and chest showed many discrete, small, erythematous nodular skin lesions. B. View of the hand showing flexion contracture at the wrist. The metacarpophalangeal joints were hyperextended and the proximal and distal interphalangeal joints showed variable flexion contractures. C. She had mild contractures of the foot joints. D. Hematoxylin and eosin stain of the skin and subcutaneous tissue biopsy specimen showing lymphocytic infiltrate permeating deep dermal collagen and subcutaneous adipose tissue, with a perivascular component (lower left part of field) consistent with panniculitis. No vasculitis or fat necrosis is seen (200 $\times$ ). (Figures A and D are reproduced with permission from the Endocrine Society. Garg, A.; Hernandez, M. D.; Sousa, A. B.; Subramanyam, L.; de Villarreal, L. M.; Dos Santos, H. G.; Barboza, O. *An Autosomal Recessive Syndrome of Joint Contractures, Muscular Atrophy, Microcytic Anemia and Panniculitis-Associated Lipodystrophy*. J. Clin. Endocrinol. Metab. 2010, 95, E58–E63.)

autosomal-recessive FPL has been reported to harbor a homozygous missense mutation in cell death-inducing DNA fragmentation factor  $\alpha$ -like effector c (*CIDE*) (64). The sc adipose tissue of the patient had multilocular, small lipid droplets in adipocytes as has been seen previously in the knockout mouse model (64,65).

**91.3.1.5 SHORT Syndrome-Associated Lipodystrophy.** The acronym of SHORT syndrome is based on several clinical features such as short stature, hyperextensibility of joints and/or inguinal hernia, ocular depression, Reiger anomaly and teething delay. Only about 30 patients have been reported to have SHORT

syndrome and both autosomal-recessive (66,67) and -dominant (68–70) modes of transmission have been reported (66–68). Features of Reiger anomaly include eye abnormalities such as hypoplasia of iris stroma, prominent Schwalbe ring, iridocorneal synechiae, micro- or megalocornea and teeth anomalies such as hypodontia, microdontia, enamel hypoplasia and atypical teeth. Some patients also manifest intrauterine growth retardation with slow postnatal weight gain, delayed speech development with normal intellect, frequent childhood illnesses, small head circumference, bilateral clinodactyly and sensorineural hearing loss.

Different patterns of fat loss have been reported. In many patients, lipodystrophy affects the face, upper extremities and sometimes the trunk, with relative sparing of the lower extremities. On the other hand, a few pedigrees with autosomal-dominant SHORT syndrome had lipodystrophy affecting only the face, gluteal region and elbows (69,70). Diabetes occurs as early as the second and third decade of life. The genetic basis remains unknown.

**91.3.1.6 Mandibular Hypoplasia, Deafness, and Progeroid Features—Associated Lipodystrophy (MDP Syndrome).** We recently reported this new syndrome distinct from MAD as these patients did not have acroosteolysis (71). All males with MDP syndrome had undescended testes and hypogonadism. One adult female showed lack of breast development. The molecular basis of this syndrome remains unknown.

**91.3.1.7 Neonatal Progeroid Syndrome (Wiedemann–Rautenstrauch Syndrome).** This is an autosomal-recessive syndrome with a total of approximately 25 reported cases (72–74). The clinical features are evident at birth and include a triangular, old-looking face with relatively large skull (progeroid appearance), prominent veins on the scalp, sparse scalp hair, large anterior fontanelle and generalized lipodystrophy. Interestingly, sc fat in the sacral and gluteal areas is spared and can be prominent (74,75). Approximately, half of them die before the age of 6 years but patients surviving up to the age of 16 years have been reported (74–77). The genetic basis remains to be elucidated.

## 91.3.2 Autosomal-Dominant Types

**91.3.2.1 Familial Partial Lipodystrophy (FPL).** Patients with FPL have variable loss of body fat from the extremities as well as from the truncal region. They follow an autosomal-dominant inheritance pattern. Recognition of affected men is very difficult because even many normal adult men appear muscular. Consequently, nearly all the reported pedigrees have been ascertained from female probands. The diagnosis can be suspected in patients with early onset of diabetes and hypertriglyceridemia in the second or third decades who do not have generalized obesity and display marked loss of fat from the extremities, especially from the gluteal region. There are several distinct subtypes of FPL as described below.

**FIGURE 91-8** FPL. A 38-year-old white woman with FPL, Dunnigan variety due to heterozygous missense mutation in the *LMNA* gene. She had loss of fat from the extremities and trunk beginning at puberty and had excess fat accumulation in the face and neck region. She has had surgical removal of fat from the chin, neck, axillae and mons pubis previously. She had acanthosis nigricans in the axillae and groins. (Reproduced with permission from Elsevier Inc. Garg, A.; Misra, A. *Lipodystrophies: Rare Disorders Causing Metabolic Syndrome*. Endocrinol. Metab. Clin. North Am. 2004, 33, 305–331.)

**91.3.2.1.1 Familial Partial Lipodystrophy, Dunnigan Type due to *LMNA* Mutations.** This lipodystrophy (OMIM #151660) was initially described by Ozer et al. (78) in a brief abstract form and later Dunnigan et al. provided a detailed phenotypic description (79). Initial reports of this syndrome described only affected females but subsequently, approximately 300–500 men and women have been reported to have FPLD (80,81). Nearly all of them are of European origin, but Asian Indian and African-American patients have also been reported (Figure 91-8).

**91.3.2.1.1.1 Clinical and Biochemical Characteristics.** It is difficult to recognize affected subjects before puberty as they have normal body fat distribution. The onset of lipodystrophy occurs during childhood or at the time of puberty and sc adipose tissue from the extremities and trunk is lost gradually. The loss of sc fat is more evident from the anterior truncal region than the posterior region (82). Concurrent with the onset of lipodystrophy, excess fat deposition occurs at the chin (“double chin”),

supraclavicular area, and face (“Cushingoid appearance”) and sometimes over the dorsocervical region (“Buffalo hump”). Magnetic resonance imaging reveals particularly prominent intermuscular (in-between the muscular fasciae) fat deposition at the level of thighs and pelvis (81). In many patients, excess fat accumulates in the intra-abdominal and intrathoracic regions. FPLD is easier to diagnose in women but the diagnosis in affected men is challenging. Some affected men do show a muscular phenotype despite no resistance exercise training and show accumulation of fat in the face and neck. About one-fifth to one-third of the patients have acanthosis nigricans, hirsutism, menstrual abnormalities, and polycystic ovaries (82).

Women seem to be particularly severely affected by the metabolic complications of insulin resistance than men (80). The prevalence of diabetes among affected women is more than 50% in pedigrees collected by us versus only about 20% in the men. Diabetes usually develops after the second decade and multiparity and excess fat deposition in the nonlipodystrophic regions, such as the chin, can be predisposing factors for diabetes (83). Affected women also have higher prevalence of hypertriglyceridemia, low serum-HDL-cholesterol concentrations, and atherosclerotic vascular disease, including coronary heart disease (80,84). Some patients also develop cardiac conduction system disturbances resulting in atrial fibrillation and congestive heart failure, manifestations of associated cardiomyopathy (85).

#### **91.3.2.1.1.2 Genetic Defect and Pathophysiology.**

Using genome-wide linkage analysis approach in five large informative pedigrees with FPLD, we reported the FPLD locus on chromosome 1q21–22 (86). Subsequently, screening for candidate genes in the 5-Mb interval, Cao and Hegele (87) reported a missense mutation, Arg482Gln, in lamin A/C (*LMNA*) gene in a Canadian pedigree. Since then, several missense mutations in *LMNA* gene have been reported in patients with FPLD, most of them substituting C-terminal residues (83,85,87–89). Interestingly, other heterozygous or homozygous mutations in *LMNA* have been implicated now in various other disorders such as idiopathic cardiomyopathy, limb-girdle, Emery–Dreifuss and congenital muscular dystrophies, Hutchinson–Gilford progeria syndrome, Charcot–Marie tooth neuropathy, MAD and atypical Werner syndrome (42,90–95). Some patients manifest overlapping clinical features of some of these disorders, which led us to propose that *LMNA* mutations cause a multisystem dystrophy syndrome affecting adipose tissue, cardiac, skeletal muscle, nerve, cutaneous and skeletal tissue (85). However, how specific mutations in *LMNA* cause adipocyte loss from certain areas of the body remains unknown. It is probably those defective interactions of lamins A and C with chromatin or other nuclear lamina proteins during the cell division leading to apoptosis and premature cell death of adipocytes. The gain of fat in nonlipodystrophic regions may be merely a compensatory phenomenon.

**91.3.2.1.1.3 Genotype and Phenotype Variation.**

Most of the missense mutations in patients with FPLD have been reported in exon 8, encoding the globular C-terminal (tail) portion of the protein (83,85,87–89,96). Arginine residue at position 482 seems to be a hot spot with approximately 75% of the patients harboring a mutation resulting in substitution of this residue to tryptophan, glutamine or leucine (83). We have reported an atypical, less-severe FPLD in a pedigree with Arg582His mutation in exon 11 (which can only affect lamin A and not lamin C) (97). We and others have found a strong association between FPLD and cardiomyopathy manifesting as congestive heart failure, atrial fibrillation and other conduction system disturbances requiring pacemaker implantation in patients with exon 1 mutations (Arg28Trp, Arg60Gly, Arg62Gly and Asp192Val) (85). Some patients manifest overlapping features of mild proximal myopathy or muscular dystrophy with slightly increased serum creatine kinase levels (85,98).

**91.3.2.1.1.4 Molecular and Differential Diagnosis.**

Since the clinical diagnosis is difficult in affected men and prepubertal boys and girls, molecular diagnosis may be helpful in them. Genotyping for mutations may be particularly important for identifying those with exon 1 *LMNA* mutations at high risk of cardiomyopathy and conduction system disturbances (85). Whether molecular diagnosis in children and adolescents can help in prevention of diabetes and other metabolic complications later in life by maintaining an active life style with intense physical activity and prevention of undue weight gain remains to be proven.

Many syndromes can present challenge in diagnosis of FPLD such as Cushing's syndrome, truncal obesity, multiple symmetric lipomatosis due to alcohol intake, acquired generalized lipodystrophy, and lipodystrophy in HIV-infected patients. Patients with FPL due to *PPARG* mutation generally have milder loss of fat from the limbs compared to those with FPLD. Subcutaneous fat from the trunk is not affected in those with *PPARG* mutations.

**91.3.2.1.2 Familial Partial Lipodystrophy due to Peroxisome Proliferator-Activated Receptor- $\gamma$  (*PPARG*) Mutation.** Candidate gene approach in many patients affected with FPL, who did not harbor a mutation in *LMNA* gene, resulted in identification of a heterozygous missense mutation, Arg397Cys, in the *PPAR $\gamma$*  gene in a 64-year-old woman with diabetes, hypertriglyceridemia, hypertension and hirsutism, who had lipodystrophy of the face and extremities (OMIM #604367) (99). Subsequently, ~30 more FPL subjects with variable presence of disorders associated with insulin resistance such as diabetes, hypertension and hypertriglyceridemia with heterozygous *PPARG* mutations have been reported (100–102). The age of onset of lipodystrophy appears to range from second decade to later during adulthood but the pattern of progression of fat loss remains to be defined. All affected subjects have been reported to have lost sc fat from the distal extremities; however, facial fat

has been variously reported to be reduced, normal or increased (99–101).

The *PPAR $\gamma$*  protein plays a central role in adipogenesis. It is a ligand-inducible nuclear transcription factor, which forms a heterodimer with the retinoid X receptor and induces transcription of adipocyte-specific genes in response to activation by hormones or other agonists (103,104). *PPAR $\gamma$*  is highly expressed in the adipose tissue, further suggesting its important role in adipose tissue function. Thus, lipodystrophy in FPL patients with missense mutations in *PPAR $\gamma$*  may be due to reduced adipogenesis. Why only selective adipose tissue depots are affected in patients with *PPARG* mutations remains unclear.

**91.3.2.1.3 Familial Partial Lipodystrophy due to v-AKT Murine Thymoma Oncogene Homolog 2 (*AKT2*) Gene Mutations.** Recently, George et al. (105) reported a heterozygous missense mutation, Arg274His, in *AKT2* gene in four subjects from a family who had insulin resistance and diabetes mellitus. The proband was a 35-year-old Caucasian female who developed diabetes mellitus at age 30 years, whereas her mother and grandmother harboring the same mutation developed diabetes during late thirties and a maternal uncle, a middle-aged person, had no diabetes but had hyperinsulinemia. Three of the four affected subjects had hypertension. The proband also had reduced body fat and partial lipodystrophy affecting mainly her extremities (Stephen O'Rahilly, personal communication), however, in depth characterization of the phenotype related to body fat distribution has not been conducted.

*AKT2* belongs to the family of phosphoinositide-dependent serine/threonine kinases and is also known as protein kinase B (PKB) (106). The three isoforms of *AKT* share more than 80% amino acid identity. *AKT1* is almost ubiquitously expressed, whereas *AKT2* is predominantly expressed in insulin-sensitive tissues and *AKT3* in the testes and brain. As compared to the overexpression of wild-type *AKT2* in 3T3-L1 mouse preadipocytes, the mutant form, Arg274His, showed markedly reduced lipid accumulation (105). Previously, a knockout mouse model has shown features of lipodystrophy, insulin resistance and diabetes with increasing age (107). Thus, taken together, lipodystrophy in patients with *AKT2* mutations may be related to reduced adipocyte differentiation and to dysfunctional postreceptor insulin signaling.

**91.3.2.1.4 Familial Partial Lipodystrophy due to Perilipin 1 (*PLIN1*) Gene Mutations.** Gandotra et al. (108) recently reported two heterozygous frameshift mutations in *PLIN1* in three families with FPL of French ancestry. A total of five patients had mutations in *PLIN1*; and all of them had fatty liver, hypertriglyceridemia and hyperinsulinemia. Three of them had diabetes mellitus. HDL-cholesterol levels were reduced in four of them. Lipodystrophy was most striking in the lower limbs and femorogluteal depot. Acanthosis nigricans was present in

all the probands and two of them also had a cushingoid appearance.

Histology of the sc adipose tissue from four patients revealed reduced size of adipocytes and increased macrophage infiltration and adipose tissue fibrosis. Retrovirally transfected preadipocytes (3T3L-1) with mutant *PLIN1* showed smaller lipid droplets compared with those transfected with the wild-type *PLIN1*. Perilipin is the most abundant protein coating lipid droplets in adipocytes. It is essential for formation and maturation of lipid droplets, storage of triglycerides and release of free fatty acids from droplets. Recent data suggest that *PLIN1* mutants fail to bind to AB-hydrolase containing 5 (*ABHD5*), which results in constitutive coactivation of adipose triglyceride lipase and increased basal lipolysis (109).

**91.3.2.1.5 Other Types of Familial Partial Lipodystrophy.** It appears that four loci for FPL, *LMNA*, *PPARG*, *AKT2* and *PLIN1* may not be able to explain the genetic basis of all the patients with FPL and there is likelihood of additional loci (99,100). In-depth characterization of the clinical phenotype related to the pattern of loss of fat in FPL patients with mutations in different genes may be helpful in identification of different phenotypes without resorting to molecular diagnosis.

**91.3.2.2 Atypical Progeroid Syndrome due to *LMNA* Mutations.** Approximately 30 patients with partial or generalized lipodystrophy, insulin resistant diabetes and progeroid features have been reported to harbor missense mutations in the *LMNA* gene (94,111,112). They also present with mottling, pigmentations and sclerosis of skin, hepatic steatosis, cardiomyopathy and valvular lesions, short stature, and deafness. Lack of breast tissue is prominent in many females while some women report premature ovarian failure.

**91.3.2.3 Hutchinson–Gilford Progeria Syndrome.** Approximately 100 patients have been reported with HGPS so far. These patients appear normal at birth but soon thereafter develop features of early aging even as neonates (113). These features include, severe alopecia, graying of hair, micrognathia, beaked nose, shrill voice, and extensive wrinkling of the skin due to loss of underlying adipose tissue, poor sexual development, joint contractures and severe atherosclerosis (113). Many of them died between the ages of 6 and 20 years. Most of the HGPS patients have synonymous heterozygous mutation Gly608Gly of the *LMNA* gene (93). This mutation presents a cryptic splice site, which leads to a mutant form of prelamin A with 50 carboxy-terminal amino acid deleted. The mutation occurred *de novo* in all patients and was demonstrated to be of paternal origin in some of the patients (93). Only one patient had a missense Gly608Ser mutation (93,114,115). Although at birth, the children with HGPS look normal, progressive and generalized loss of body fat occurs later and they develop severe lipodystrophy with increasing age. The precise pattern of body fat loss in patients with HGPS remains to be studied.

### 91.3.3 Other Extremely Rare Types of Genetic Lipodystrophies

An autosomal-dominant variety of generalized lipodystrophy with acromegaloid features and onset after 18 years of age was reported in a pedigree from Brazil (116). We have also observed lipodystrophy of the lower extremities in two siblings with unbalanced translocation involving chromosome 8p and 10p.

## 91.4 LONG-TERM COMPLICATIONS

Patients with lipodystrophies are predisposed to long-term complications of diabetes, i.e. nephropathy, retinopathy and neuropathy. A few patients with CGL have developed end-stage renal disease requiring renal transplantation (117). Blindness due to retinopathy has also been seen in some. Many patients develop recurrent attacks of acute pancreatitis due to extreme hypertriglyceridemia. In some patients, hepatic steatosis can result in further liver dysfunction such as steatohepatitis and cirrhosis. Patients with CGL, type 4 have been reported to have died suddenly most likely due to arrhythmias (39). Some patients with MAD die during childhood of unknown reasons and while some others die during early adulthood due to complications of renal failure due to focal segmental glomerulosclerosis (118,119). Accelerated atherosclerosis causing coronary heart disease, peripheral vascular disease and cerebrovascular accidents has been noted in patients with FPL, particularly among women (6,80,84,120). Other patients with HGPS are also prone to develop severe atherosclerosis.

## 91.5 TREATMENT OPTIONS

Management of severe insulin resistance and its complications, such as severe diabetes, hypertriglyceridemia, hepatic steatosis, polycystic ovarian disease and acanthosis nigricans, in patients with lipodystrophies is challenging. Because many patients may have abnormally elevated serum alanine aminotransferase and aspartate aminotransferase levels indicating liver dysfunction, the choice of therapeutic agents may differ. Briefly, various therapeutic options available are as follows.

### 91.5.1 Diet and Physical Activity

Metabolic complications such as dyslipidemia, diabetes and hepatic steatosis can be mitigated with reduced energy intake and increased physical activity. Patients with partial lipodystrophies must avoid gain of excess fat in nonlipodystrophic regions to reduce their risk of developing metabolic complications. However, appetite is difficult to control in young patients with generalized lipodystrophies. Children also require energy for growth and development and thus diet should allow for adequate growth in young patients. For patients with extreme

hypertriglyceridemia, low-fat diet is appropriate to avoid formation of chylomicrons. Whether extremely low-fat diets will be beneficial for CGL patients remains to be investigated. To reduce risk of atherosclerosis, attempt should be made to reduce low-density-lipoprotein cholesterol levels (or non-HDL cholesterol levels in hypertriglyceridemic patients) to minimum by limiting intake of saturated and trans fats as well as cholesterol (121).

### 91.5.2 Drug Therapy

Diabetes control can be achieved with oral hypoglycemic drugs or insulin. Metformin is particularly attractive since it improves insulin sensitivity, reduces appetite and can induce ovulation in patients with polycystic ovarian disease. However, efficacy of metformin therapy has not been systematically studied in patients with lipodystrophies. On the other hand, thiazolidinediones such as rosiglitazone and pioglitazone, which are PPAR $\gamma$  agonists, may be particularly attractive for FPL patients with *PPARG* mutations; however, limited experience in two such patients resulted in equivocal results (101). In most patients with severe insulin resistance, high doses of insulin remain the mainstay of therapy. Rigorous effort to improve glycemic control is needed to manage hypertriglyceridemia.

If hypertriglyceridemia persists despite good glycemic control, fibric acid derivatives (PPAR $\alpha$  agonists) such as gemfibrozil, fenofibrate or clofibrate are helpful in reducing serum triglycerides. For those unable to tolerate fibrates or with liver dysfunction,  $\omega$ -3 polyunsaturated fatty acids from fish oils should be used in high doses (5–10 g/day). In some patients, a combination of low-dose statins and fibrates can be tried for maximal reduction of non-HDL cholesterol levels. Niacin should be avoided as it can induce insulin resistance and can exacerbate hyperglycemia (122). In women, oral estrogens should also be avoided as they can induce extreme hypertriglyceridemia and acute pancreatitis (6).

Recently, sc recombinant leptin therapy has been reported to be efficacious in improving hyperglycemia, dyslipidemia and hepatic steatosis in patients with severe lipodystrophies and hypoleptinemia (8,123–125). Leptin therapy reduces appetite and results in substantial weight loss, which seems to be a primary mechanism for improving metabolic complications (8). However, leptin therapy is still investigational.

### Biography

**Abhimanyu Garg, MD** is a professor of Internal Medicine and is Chief, Division of Nutrition and Metabolic Diseases at UT Southwestern. He holds a Distinguished Chair in Human Nutrition Research. Dr Garg's research has focused on the problems of nutrition for patients with diabetes and management of dyslipidemia in patients with type 2 diabetes. In addition, he has contributed to the understanding of the relationship of body fat distribution and insulin resistance. He has carefully characterized the phenotype of various disorders of adipose tissue, called lipodystrophies, which has led to discovery of many novel genes for these disorders. Dr Garg's group identified deficiency of AGPAT2 enzyme, which is critical for triglyceride and phospholipid biosynthesis, as the cause of congenital generalized lipodystrophy, type 1. His group also linked peroxisome proliferator-activated receptor- $\gamma$  gene, the key adipocyte differentiation transcription factor, to familial partial lipodystrophy. His team has also identified the second locus for mandibuloacral dysplasia, i.e. zinc metalloproteinase (ZMPSTE24), that is responsible for posttranslational processing of prelamin A to its mature form lamin A. Recently, he discovered mutation in proteasome subunit, beta-type 8 (*PSMB8*) as the underlying basis of a novel autoinflammatory lipodystrophy syndrome. He demonstrated that patients with generalized lipodystrophy have profound leptin deficiency and proposed that leptin deficiency might contribute to the metabolic complications in the disorder. This led him to initiate a collaborative trial that demonstrated dramatic improvement in hyperglycemia, dyslipidemia, and fatty liver with leptin therapy.

## Amino Acid Metabolism

*Raymond Y Wang, William R Wilcox and Stephen D Cederbaum*

Division of Metabolic Disorders, CHOC Children's Hospital, Orange, CA, USA

This article is a revision of the previous edition article by William R Wilcox and Stephen D Cederbaum, volume 2, pp 2159–2190, © 2007, Elsevier Ltd.

The inborn errors of amino acid metabolism are a family of genetic conditions in which an enzyme deficiency typically results in the accumulation of a ninhydrin-positive amino acid. They are conceptually identical to disorders caused by enzyme defects that result in the accumulation of the organic acid intermediates (see Chapter 97). As our understanding of the dynamics of amino acid metabolism grows, simplistic notions of metabolic pathways solely as conduits for elimination of excess substrate have been abandoned. We now realize that most, if not all, of these reactions are highly regulated and integrated into the total fabric of metabolic homeostasis in which amino acids play an important role. Nevertheless, such considerations are largely beyond the scope of this concise overview and are covered in more detail in the work by Scriver and colleagues (1), the standard reference work on these and other inborn errors of metabolism and one that explores the physiologic interactions more fully.

This chapter strives to highlight the clinical, biochemical, molecular, and pathologic features of these inborn errors of metabolism. Although approached in a reductionist manner, providing quick reference for a geneticist with a patient carrying the diagnosis, we realize that in practice, the undiagnosed patient presents to the physician with symptoms in search of an explanation. Based on the clinical features described in the following sections, the physician must decide whether specific diagnostic tests, plasma amino acids, urine organic acids, and ammonia for acutely ill patients, or urinary amino acids for those with more insidious clinical symptoms, should be performed. A deeper understanding of many amino acid-related disorders necessitates the inclusion in this sixth edition of a new section about serine biosynthetic disorders as well as appreciable expansions of the sections regarding cobalamin defects, proline metabolism, citrin deficiency, and many more.

In addition, we have updated this chapter with results of clinical trials, as advances in therapeutics for many

of the aminoacidopathies have allowed for significant changes in patient management and outcomes. Much of the current information on the molecular aspects of these disorders can be accessed through the Online Mendelian Inheritance in Man database (OMIM; <http://www.ncbi.nlm.nih.gov/omim>) or the GeneTests database (<http://www.ncbi.nlm.nih.gov/sites/GeneTests/>).

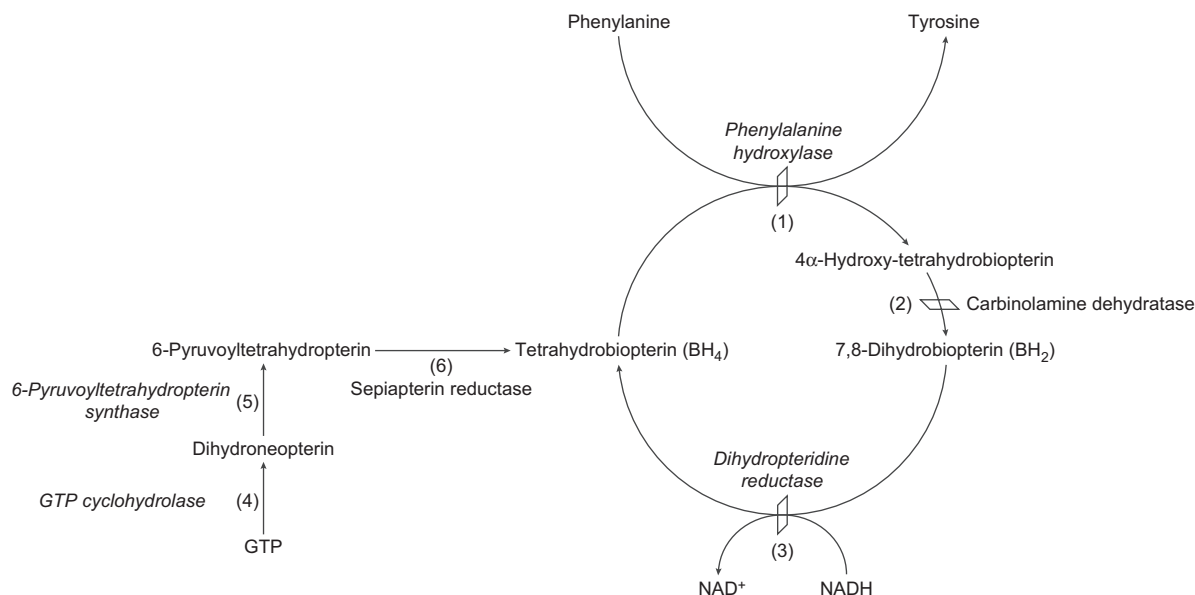

## 92.1 DISORDERS OF PHENYLALANINE METABOLISM

### 92.1.1 The Hyperphenylalaninemias

Folling, a Norwegian chemist, first recognized the existence of a disorder of phenylalanine metabolism in 1934 (2). He found phenylpyruvic acid and phenylacetic acid in the urine of mentally retarded patients in an institution for the retarded. This condition was eventually called phenylketonuria (PKU) and is a cornerstone of research in clinical and biochemical genetics. We now recognize several genetic entities that can cause an elevation in blood phenylalanine and mimic the clinical phenotype of PKU. Each disorder interferes with the hydroxylation responsible for the conversion of phenylalanine to tyrosine. Each disorder causes an elevation in phenylalanine concentration in the blood; collectively, they are referred to as the hyperphenylalaninemias. These disorders are reviewed in detail by Scriver and Kaufman (3) and Blau and colleagues (4).

### 92.1.2 Phenylalanine Hydroxylase Reaction

Phenylalanine is hydroxylated to tyrosine by the enzyme phenylalanine hydroxylase (PAH). The reaction requires molecular oxygen, and tetrahydrobiopterin is the active cofactor (5). The tetrahydrobiopterin is generated de novo in humans from guanosine triphosphate (GTP) by a complex series of enzymatic reactions (Figure 92-1).

**FIGURE 92-1** Regulation of PAH activity. (1) Phenylalanine is converted to tyrosine by the holoenzyme, PAH. PAH requires tetrahydrobiopterin (BH<sub>4</sub>) as an active cofactor and is recycled by the sequential actions of (2) PCD and (3) DHPR. BH<sub>4</sub> is synthesized *in vivo* through a complex series of steps that involve (4) GTP-CH, (5) PTPS, and (6) SR. Genetic defects at any of these steps except for (6) may be associated with hyperphenylalaninemia.

The products of the PAH reaction are tyrosine and an oxidized biopterin, 4α-hydroxy-tetrahydrobiopterin. Tetrahydrobiopterin is regenerated by the sequential actions of carbinolamine dehydratase and dihydropteridine reductase (DHPR). In humans, the conversion of phenylalanine to tyrosine occurs primarily, if not entirely, in the hepatocytes. The functional enzyme exists as a homodimer or homotetramer and has catalytic, regulatory, and tetramerization domains (6).

### 92.1.3 Classic PKU

Classic PKU (OMIM 261600) occurs when an individual expresses 5% or less of normal PAH activity in the hepatic tissue. The enzyme deficiency was first documented by Jervis (7) and subsequently by others. If left untreated, patients with classic PKU develop mental retardation, eczema, hypopigmentation, and neurologic symptoms. Knox (8) reviewed the intellectual results of untreated children and adults with PKU and concluded that most would have an intelligence quotient (IQ) in the severely retarded range. On screening approximately 250,000 blood samples submitted to the Massachusetts State Health Laboratory for syphilis testing, Levy and colleagues (9) found only three persons with an elevated blood phenylalanine level, and each was retarded. Thus, normal intelligence is infrequently achieved in persons with PKU who remain untreated.

The characteristic “mousey” odor present in some untreated persons with PKU is due to the excretion of phenylacetic acid. The hypopigmentation of the skin and hair occurs because of competitive inhibition of tyrosine hydroxylase by the increased concentration of phenylalanine. The inhibition of tyrosine hydroxylase activity

prevents the conversion of tyrosine to dopa and the subsequent formation of melanin. Thus, affected and untreated individuals have been described as having blue eyes, blonde hair, and pale skin.

Neurologic symptoms in untreated persons with PKU include hypertonicity, irritability, agitated behavior, tremors, hyperactivity, and occasional seizures; some are considered autistic. The precise mechanisms that cause the defective myelin formation, neurologic abnormalities, and mental retardation are unknown.

In most of the developed countries, infants are being screened for PKU by measurement of blood phenylalanine during the newborn period, using either a fluorometric or a microbiologic assay. Patients with classic PKU eventually demonstrate a persistent elevation in phenylalanine levels, greater than 1000–1200 μM (16–20 mg%, normal < 80 μM or 1.3 mg%), in their blood while receiving a normal dietary intake of protein. Their plasma tyrosine will be within the normal range, and hydroxyphenylacetic acid and phenylpyruvic acid will eventually be detectable in the urine. Plasma studies have now completely supplanted those in the urine.

Most infants with an elevated blood phenylalanine level detected through a screening program do not have classic PKU; rather, they have a transient or a mild form of hyperphenylalaninemia, which is usually benign and does not require therapy.

Most newborn screening programs had used a cutoff value of 120 or 240 μM (2 or 4 mg%) as an indicator of a “positive” test. With the advent of screening by tandem mass spectrometry, by which both phenylalanine and tyrosine can be measured with great accuracy, the phenylalanine to tyrosine ratio is becoming an increasingly

important measurement, maintaining a high degree of sensitivity (even with early discharge) while increasing specificity (10). The newborn screening samples for healthy infants are typically collected on the day of discharge from the hospital. In the recent past, this usually occurred at 3–5 days of age, and because the blood phenylalanine inevitably rose above  $240\ \mu\text{M}$  in infants with PKU by day 3 of life, it was a reliable and sensitive assay. With the recent changes in healthcare policy in most western countries, infants are being discharged earlier than 3 days, sometimes at less than 24 h of age. Because of the advances in screening algorithms and technology, repeat screening at 4 weeks of age is no longer required, even with early postnatal testing (11).

Classic PKU is inherited in an autosomal recessive manner and occurs in approximately 1:10,000 births in populations of western European origin. In these populations, the PAH-deficient alleles can be considered a polymorphism because the gene frequency ( $q$ ) exceeds 0.01 and the heterozygote frequency ( $2pq$ ) is 0.02 or greater. The highest frequency for PKU is in Turkey, with an incidence of 1 in 2600 newborns; Scotland has a frequency of 1 in 5300 newborns, with most other European countries reporting a frequency of 1 in 10,000 for newborns. China has an incidence of 1 in 16,000; PKU in Japan is relatively rare, with a reported frequency of 1 in 143,000 births. PKU is similarly rare in Ashkenazi Jews, Finns, and blacks.

More than 350 mutations have been identified to be associated with the PKU phenotype. Most of these mutations have been identified in exons 6–12 (see data in OMIM, Scriver (1), and the PAH database (<http://www.pahdb.mcgill.ca/>)).

No single mutation accounts for the majority of cases in persons with the PKU phenotype. Clustering of specific mutations occurs within certain ethnic groups or certain geographic regions. For instance, most affected French Canadians have the p.M1V mutation. Affected persons from eastern Europe commonly bear the p.R408W mutation. In the data available from the Chinese population, a restricted number of mutations have been identified, most commonly associated with a common haplotype (haplotype 4) (12).

For the white population of northern European origin, most PKU patients were initially identified as having mutations on a background of chromosomes of similar haplotype, either haplotype 2 or haplotype 3. Direct identification of mutations found a plethora of alterations rather than a single common mutation. Recurrent mutations found in PAH are p.M1V, p.R261Q, p.R408W, p.Y414C, c.1315+1G>A, and c.1066-11G>A. One study was able to confirm the genotype of both alleles in 35% of PKU patients from the Midwest region of the United States (13). In general, there appears to be a good correlation between the severity of protein change, determined by mutant genotype and the degree of phenylalanine intolerance. However, the exceptions are frequent enough that routine genotyping of patients does not appear to be clinically useful (14,15). A

great source of variability in cognitive outcome may lie in interindividual variability in phenylalanine transport from the blood into the brain. Rare individuals have biochemically classic PKU yet normal intelligence, in spite of high plasma phenylalanine levels because of lower levels of phenylalanine transport into the brain (16).

Heterozygote detection using plasma phenylalanine and tyrosine levels, under standard conditions, has been possible but imprecise (17). Realistically, carrier testing is not frequently performed due to the existence of newborn screening for ascertainment of subsequent children and limited clinical utility of PAH genotyping.

Accurate diagnosis of infants identified from newborn screening programs is critical to establish appropriate therapeutic regimens. Most infants with an elevated blood phenylalanine above the screening laboratories' selected threshold will not have PKU. False-positive tests generally occur in infants who are premature, receive hyperalimentation, or have liver disease, or the condition is of a transient nature and occurs for unknown reasons. Fewer than 30–50% of infants would be confirmed as having persistent hyperphenylalaninemia. We recommend the following as a practical approach in the evaluation of infants with a positive screening test.

- (1) A single value of  $120\text{--}360\ \mu\text{M}$  and/or an elevated phenylalanine to tyrosine ratio: repeat the screening test.
- (2) A single value above  $360\ \mu\text{M}$ : quantify blood phenylalanine and tyrosine and
  - (a) if phenylalanine and phenylalanine to tyrosine ratio are all still elevated, then evaluate for persistent hyperphenylalaninemia (step 3)
  - (b) if tyrosine is elevated, then evaluate the causes of hypertyrosinemia
  - (c) if phenylalanine and tyrosine have rapidly normalized, then consider maternal hyperphenylalaninemia.
- (3) Persistent hyperphenylalaninemia (greater than  $360\ \mu\text{M}$ ) and normal tyrosine: repeat quantification of plasma phenylalanine: collect urine for quantification of pterin metabolites and quantify DHPR in a whole blood sample or from a dried blood spot.

We believe that the above-mentioned procedure is a rational and convenient approach to diagnosis within the capability of programs that screen newborns for PKU. More elaborate studies of mutation analysis of the PAH gene or liver biopsies to measure the activity of the PAH enzyme are not required for routine diagnosis and decisions for appropriate therapy. The quantification of urinary pterin metabolites and blood DHPR should be performed in one of the selected laboratories that routinely handle a large volume of samples for diagnostic purposes.

Dietary therapy has proved effective in preventing mental retardation in patients with PKU. In long-term studies in the United Kingdom, Canada, and the United States, the restriction of dietary phenylalanine within 30 days of birth and continuing for 12 years has resulted in

intelligence comparable to, or slightly below, that of normal sibs (18,19). It is currently believed that restriction of dietary phenylalanine should begin as soon after birth as possible and should continue throughout life. Recent studies suggest a reversible diminution in performance in almost all PKU patients when plasma phenylalanine rises (20), particularly in language skills (21). In some cases, permanent loss of intellectual achievement results from dietary termination. The diet should be managed by a competent team consisting of a nutritionist, a physician, and a person with skills in family dynamics to ensure dietary compliance. It had been recommended that blood phenylalanine levels of 120–600  $\mu\text{M}$  (2–10 mg%) were satisfactory for achieving normal development in patients with PKU. It is now believed that blood phenylalanine levels should be maintained below 360  $\mu\text{M}$  (6 mg%) (11,22). Although desirable, many families are unable to achieve such levels consistently.

Newborns with persistent hyperphenylalaninemia of greater than 360–600  $\mu\text{M}$  (6–10 mg%) should be treated. The exact quantity of phenylalanine in the diet needs to be individually determined because the variation in genotype, among other factors, influences phenotype. Most affected infants can be placed on a special commercial formula deficient in phenylalanine and specifically designed for children with PKU to lower their blood phenylalanine below predetermined therapeutic levels. At that point, the formula needs to be supplemented with an infant formula or milk to supply a phenylalanine concentration of approximately 60–90 mg/kg/day. This quantity of phenylalanine needs to be individually adjusted to maintain the blood phenylalanine at 60–360  $\mu\text{M}$  (1–6 mg%) on a consistent basis. Once stabilized, blood values determined once a month are recommended for monitoring dietary compliance and making nutritional adjustments. Most children and adults require a daily phenylalanine intake of 200–500 mg/day from all food sources to maintain blood phenylalanine within the therapeutic range. A lifetime commitment to the use of a special formula, a vegetarian-style diet, and the use of low-protein foods are required for the prevention of neurologic sequelae from persistent hyperphenylalaninemia. Compliance of families and patients, particularly during the teenage years, may be a problem.

The treatment of PAH deficiency is continuing to evolve with development of novel therapies. Supplementation with tetrahydrobiopterin ( $\text{BH}_4$ ) improves phenylalanine tolerance in many patients, particularly in patients with milder mutations, but responsiveness to  $\text{BH}_4$  cannot be reliably predicted from the mutations in a given patient (23,24). Supplementation with  $\text{BH}_4$  not only can improve protein activity with  $\text{K}_m$  mutations but also can act as a chemical chaperone to improve folding of some types of mutant PAH (25). Multicenter, randomized, double-blind, placebo-controlled clinical trials have been performed, which showed a percentage of PKU patients

receiving a sapropterin hydrochloride (6R-tetrahydrobiopterin) concentration of 20 mg/kg/day, demonstrating increased phenylalanine tolerance of 17.7 mg/kg/day compared to baseline (26). While  $\text{BH}_4$  is most effective in patients with hyperphenylalaninemia or mild PKU and therefore will have the least impact on their treatment, a small percentage of classic PKU patients respond to treatment with increased phenylalanine tolerance. The degree of response, however, is slight and patients continue to require phenylalanine-restricted diets with synthetic protein supplementation. Enteric enzyme therapy with modified PAH or bacterial phenylalanine ammonia-lyase is being developed, converting phenylalanine to innocuous substances in the body (27). When it is perfected, gene therapy will be the ultimate cure for PAH deficiency.

Children born to mothers with PKU have a high risk of having mental retardation or congenital defects. Approximately 90% of offspring born to mothers with classic PKU who have not received dietary restriction of phenylalanine during their pregnancy will be affected with mental retardation, microcephaly, and impaired growth (28,29). Fourteen percent of these children will have cardiac malformations (30).

Ensuring preconceptional treatment is a significant public health issue for women with PKU. Failure to resolve the issue and to allow women with PKU to give birth to children who are mentally damaged could largely reverse the major societal gains that have been achieved during the past 40 years. Women with PKU can have normal children if satisfactory dietary intervention can maintain blood phenylalanine levels at less than 360  $\mu\text{M}$  (6 mg%), both before and during pregnancy (31–33). For pregnant women who have remained on their diet before conception and who continue to maintain satisfactory blood phenylalanine values of less than 360  $\mu\text{M}$  during pregnancy, a successful outcome can be expected. For those women who have been less diligent in maintaining their diet or who have been untreated for a number of years, returning to a phenylalanine-restricted diet can be difficult and requires considerable medical and social support to assist them in achieving satisfactory phenylalanine values (34). Mild hyperphenylalaninemia with untreated plasma phenylalanine no greater than 360  $\mu\text{M}$  (6 mg%) does not appear to pose a risk to the fetus and does not require treatment (35).

Commercial formulas are available to help the older patients return to diet. Additional supplements of tyrosine and possibly branched-chain amino acids (BCAAs) may be required during pregnancy. Administration of these supplements requires careful amino acid monitoring of plasma and frequent adjustments of formula composition and food selection.

The problem of maternal PKU emphasizes the need of governmental and regional programs to maintain contact with women who have hyperphenylalaninemia and to

ensure that these women are aware of the risks of pregnancy and of the personal discipline required to achieve a child free of the teratogenic effects of hyperphenylalaninemia in utero. Programs responsible for newborn screening and the management of persons with PKU should ensure that appropriate resources are in place to counsel, support, and manage women with PKU who may elect to become pregnant.

### 92.1.4 Defects in Biopterin Metabolism

Not all children with persistent hyperphenylalaninemia have a primary defect in the PAH gene. Approximately 1% of infants ascertained with persistent phenylalanine levels above 600  $\mu$ M (10 mg%) will suffer from neurologic deterioration, despite adequate and timely restriction of phenylalanine intake. Most of these children lack adequate levels of tetrahydrobiopterin, owing either to a defect in dihydrobiopterin biosynthesis or to a deficiency of DHPR (see [Figure 92-1](#)) (36). Tetrahydrobiopterin is an indispensable cofactor for PAH activity and serves as an essential cofactor for tyrosine and tryptophan hydroxylase reactions. Decreased activity of these two enzymes results in low levels of two neurotransmitters in the brain: dopamine and serotonin (37), resulting in neurologic damage, mental retardation, and, in many instances, death. Disorders that involve biopterin synthesis or regeneration have been called “atypical or malignant PKU (or hyperphenylalaninemia).”

In vivo synthesis of the active cofactor, BH<sub>4</sub>, is accomplished by the sequential activity of GTP cyclohydrolase (GTP-CH), 6-pyruvoyltetrahydropterin synthase (PTPS) and sepiapterin reductase (SR). Approximately 60% of patients with documented disorders of biopterin metabolism have a deficiency of PTPS (38). Most of the remainder have defects in the recycling of BH<sub>2</sub> to BH<sub>4</sub> by DHPR and pterin-4 $\alpha$ -carbinolamine dehydratase (PCD) (see [Figure 92-1](#)).

### 92.1.5 PTPS Deficiency

PTPS deficiency (OMIM 261640) is now typically identified by newborn screening programs when infants with hyperphenylalaninemia are found to have abnormal biopterin metabolites in their urine. The urine and cerebrospinal fluid (CSF) contain a high ratio of neopterin to biopterin. Levels of CSF neurotransmitter metabolites homovanillic acid (HVA, derived from catecholamines) and 5-hydroxyindoleacetic acid (5-HIAA, derived from serotonin) are low. The inability to form BH<sub>4</sub> from GTP results in impairment of PAH activity, with a resultant elevation in blood phenylalanine levels.

Infants with PTPS deficiency develop neurologic symptoms despite normalization of blood phenylalanine levels. They may be microcephalic and small for gestational age. They will typically develop increased tone in the arms and legs, poor truncal tone, irritability, difficulty

swallowing, hyperthermia, seizures, and delayed mental development. A parkinsonian movement disorder may be apparent in some children.

Treatment of PTPS deficiency should consist of daily replacement of BH<sub>4</sub> (2–5 mg/kg/day), levodopa, 5-OH-tryptophan, and carbidopa (39). Although most children with PTPS deficiency improve with treatment, many have sustained permanent central nervous system (CNS) damage by the time diagnosis had been correctly established and treatment begun. The damage may even be prenatal (40). Treatment efficacy must be monitored continually and dosage of replacement medicines adjusted. Rare patients with hyperphenylalaninemia due to PTPS deficiency have normal neurotransmitter metabolite levels and can be treated with BH<sub>4</sub> alone (40).

PTPS deficiency is inherited as an autosomal recessive disorder. The enzyme has been documented to be deficient in the hepatic tissue of affected patients (41,42) and in erythrocytes (43). The enzyme is a tetramer of identical subunits; heterozygotes may have less than 50% of activity due to heteropolymeric inactivation of the complete enzyme by the mutant. A number of independent mutations have been identified in patients with deficiency of this enzyme (44).

### 92.1.6 GTP-CH Deficiency

GTP-CH is the rate-limiting first step of BH<sub>4</sub> biosynthesis. GTP-CH deficiency (OMIM 128230, 233910) can occur as a dominant or recessive condition. The dominant condition is one cause of dopa-responsive dystonia, another being tyrosine hydroxylase deficiency or Segawa syndrome. Patients with dominant GTP-CH deficiency do not have hyperphenylalaninemia; rather, after a period of normal gross motor development, they develop appendicular dystonia with gait disturbance and hyperreflexia in childhood, typically by age 6. Normal intelligence is retained. The dystonia responds dramatically following daily treatment with small doses of levodopa. Later development of parkinsonism and extrapyramidal symptoms may result in misdiagnosis as “juvenile Parkinson’s disease,” but the disorder is distinguished from true Parkinson’s by lack of dyskinesia, on–off effect, or resistance to levodopa therapy. The recessive form of GTP-CH deficiency is typically picked up by newborn screening with hyperphenylalaninemia, although exceptions exist (45–47).

Patients with recessive GTP-CH deficiency demonstrate much more neurologic dysfunction than the dominant form, with early-onset developmental delay, seizures, tremors, truncal hypotonia with appendicular hypertonia, and autonomic dysfunction (38,48,49). Similar to 6-PTPS deficiency, the recessive mutations in GTP-CH lead to a severe deficiency in the synthesis of BH<sub>4</sub> from GTP (see [Figure 92-1](#)). In addition to persistent hyperphenylalaninemia, both biopterin and neopterin levels are low in body fluids such as urine, plasma,

and CSF. A normal neopterin to biopterin ratio is preserved. CSF neurotransmitter metabolite analysis typically also shows low HVA and 5-HIAA levels. Treatment of recessive GTP-CH deficiency consists of supplementation with oral BH<sub>4</sub> in addition to levodopa/carbidopa and 5-hydroxytryptophan.

### 92.1.7 DHPR Deficiency

A deficiency of DHPR (OMIM 261630) is the second most common defect of biopterin metabolism. DHPR deficiency accounts for approximately 0.5% of infants documented to have persistent hyperphenylalaninemia.

DHPR is required for the regeneration of BH<sub>4</sub> from BH<sub>2</sub>. A deficiency of DHPR can be expected to produce a secondary deficiency of PAH, tyrosine hydroxylase, and tryptophan hydroxylase, with the metabolic phenotype of hyperphenylalaninemia and CNS deficiency of catecholamines and serotonin. Folate metabolism is also altered because DHPR is responsible for maintaining folate in its active tetrahydrofolate form (50).

The clinical consequences of DHPR deficiency are serious. Affected children develop seizures, microcephaly, and progressive neurologic degeneration despite apparent satisfactory management of their hyperphenylalaninemia, if phenylalanine restriction is the only form of therapy (51). Oculogyria, diurnal variation, hypersalivation, and hyperthermia, which are symptoms of neurotransmitter deficiency, also manifest. They are also at risk of sudden death, possibly because of unregenerated BH<sub>2</sub> accumulation and folate deficiency. They have low levels of HVA and 5-HIAA in the CSF and urine (42).

The disorder is inherited in an autosomal recessive manner. A number of different mutations have been identified, which include point mutations, small deletions, and insertions (52,53). The identification of heterozygotes for DHPR deficiency in families with an affected child can be achieved by direct enzymatic assay using erythrocytes or leukocytes (54,55).

The diagnosis of DHPR deficiency can be established by either molecular sequencing of the gene or more rapidly via direct measurement of DHPR activity in leukocytes or erythrocytes. The most efficient manner is by enzyme assay using a dried blood spot on filter paper (56) as part of the routine evaluation of all infants with hyperphenylalaninemia. Although in some infants, alterations in urinary biopterin profiles are a clue to the diagnosis, it is estimated that one-third of the infants with DHPR deficiency will be missed if urine biopterin levels alone are relied on for detection (41,42).

Children with DHPR deficiency can benefit from therapy, especially if the condition is detected early and treated aggressively but remain significantly delayed in development (57). It is important to restrict the phenylalanine levels in the diet to achieve near-normal blood levels and to supply adequate precursors of the neurotransmitters. In addition to neurotransmitter replacement, as

described for PTPS deficiency, folinic acid 12.5 mg/day is recommended (58). Some may also improve following treatment with BH<sub>4</sub> (59).

### 92.1.8 PCD Deficiency

PCD and DHPR are required for the conversion of oxidized BH<sub>2</sub> back to active BH<sub>4</sub>. Deficiency of PCD (OMIM 264070) results in neonatal-onset hyperphenylalaninemia that is transient, even with a normal diet. Clinically, most patients with PCD have normal growth and development, though some have been reported with transient hypotonia (60). Patients with PCD deficiency excrete 7-biopterin, also known as primapterin (47). CSF neurotransmitter metabolite levels are normal.

### 92.1.9 SR Deficiency

Although SR deficiency does not cause hyperphenylalaninemia, it is still included here as an inborn error of BH<sub>4</sub> synthesis. The mechanism for absence of hyperphenylalaninemia is the existence of aldose reductase, carbonyl reductase, and dihydrofolate reductase in the liver but not the CNS, allowing phenylalanine hydroxylation via peripheral conversion of sepiapterin to BH<sub>4</sub> (39,61). Phenylalanine loading tests in patients with SR deficiency are abnormal, however, and CSF neurotransmitter analysis demonstrates low levels of HVA and 5-HIAA, while neopterin and BH<sub>4</sub> levels may be normal. SR deficiency is one of the rare forms of BH<sub>4</sub> biosynthetic deficiency, with less than 40 cases currently well described. While most patients present with the typical dopa-responsive dystonia phenotype of the other neurotransmitter synthetic deficiencies, others have presented with somnolence, psychomotor retardation, and gait disturbance later in childhood (62,63). Unfortunately, SR deficiency does not respond well to BH<sub>4</sub> supplementation; rather, the treatment of the disorder centers around provision of L-dopa/carbidopa and 5-hydroxytryptophan.

## 92.2 DISORDERS OF TYROSINE METABOLISM

Approximately one-half of the available tyrosine in humans is formed from the oxidation of phenylalanine. Tyrosine is essential for the synthesis of protein, the synthesis of thyroid hormones, the formation of melanin pigment, and the production of dopamine and catecholamines. Tyrosine is metabolized through a series of oxidative steps to form acetoacetic and fumaric acids (Figure 92-2). In the presence of excess dietary protein, the rate-limiting enzyme for the pathway is tyrosine aminotransferase (TAT). Enzyme deficiencies within the catabolic pathway may cause accumulation of tyrosine or a tyrosine product. Severe liver disease may elevate plasma tyrosine levels as well. The only common disorder of tyrosine metabolism is transient neonatal tyrosinemia, a

**FIGURE 92-2** The tyrosine metabolic pathway. Enzymes involved are (1) TAT; (2) *p*-OH-phenylpyruvic acid dioxygenase; (3) homogentisic acid oxidase; (4) maleylacetoacetic acid isomerase; and (5) fumarylacetoacetic acid hydrolase.

problem of delayed developmental synthesis or stability of *p*-hydroxyphenylpyruvic acid (pHPPA) dioxygenase. The other known disorders are genetically determined but are uncommon. These disorders are reviewed by Mitchell and colleagues (64,65).

### 92.2.1 Transient Neonatal Tyrosinemia

In the 1960s, it was estimated that 30% of premature infants and 10% of full-term infants would develop neonatal tyrosinemia. Neonatal tyrosinemia does not occur because of a genomic mutation in the tyrosine catabolic but is a result of an infant's interaction with the environment. Gestational age rather than birth weight was the most consistent predisposing factor. It is more common in Alaskan Eskimos and Inuit Indians, but this may be due to ascorbate deficiency, rather than a genetic predisposition. Neonatal tyrosinemia, per se, is not believed to be associated with clinical symptoms, but some studies suggested reduced intellectual performance.

The incidence of significant neonatal tyrosinemia has decreased in recent years because of changes in feeding practices of newborns. The major environmental factors associated with neonatal tyrosinemia are prematurity, a diet containing protein concentration of greater than 3 g/kg/day, and deficient intake of vitamin C. Cow's milk is less widely used and would typically supply a protein concentration of 5 g/kg/day or greater. Modern infant formulas supply a protein concentration of 2–3 g/kg/day, similar to breast milk feeding, and are supplemented with vitamin C.

Transient neonatal tyrosinemia is due to decreased activity of pHPPA dioxygenase, an ascorbate-dependent enzyme. The amount of enzymatic activity in the hepatic tissue increases with increasing gestational age, often reaching normal levels only after birth. Thus, young infants may have insufficient pHPPA dioxygenase to metabolize the pHPPA formed from tyrosine. Tyrosinemia, if significant,

may be treated by lowering the dietary protein to 2 g/kg/day to decrease the formation of pHPPA from tyrosine and administering 100 mg of ascorbic acid per day to stabilize those enzyme molecules that have been synthesized. Most infants with neonatal tyrosinemia will promptly lower their plasma tyrosine concentration to the normal range (less than 0.1 mM) with these two maneuvers.

### 92.2.2 Hepatorenal Tyrosinemia

Hepatorenal tyrosinemia (OMIM 276700), or tyrosinemia I, is a rare and potentially lethal inborn error of metabolism caused by a deficiency of fumarylacetoacetate hydrolase (FAH). This enzyme catalyzes the conversion of fumarylacetoacetate to fumarate, a Krebs cycle intermediate, and acetoacetate, a ketone body. FAH deficiency leads to accumulation of fumarylacetoacetate, its precursor maleylacetoacetate, and a decarboxylation product succinylacetone, all of which are toxic to the liver and kidneys (see Figure 92-2). Succinylacetone is also a potent inhibitor of  $\delta$ -aminolevulinic acid (ALA) dehydratase, which leads to reduction in heme synthesis. Clinical symptoms of tyrosinemia I span a continuum of severity. The most severe cases can present in the neonatal period and typically prior to the sixth month of age, with irritability, poor feeding, and failure to thrive. Sometimes the characteristic “boiled cabbage” odor is present. Laboratory investigations will identify elevations in liver transaminases, prolonged prothrombin and partial thromboplastin bleeding times, and marked elevation in serum  $\alpha$ -fetoprotein (AFP, usually >100,000 ng/mL) that are hallmarks of the hepatotoxic effects of fumarylacetoacetate and its adducts. Without treatment, the infantile-onset patients will rapidly develop fulminant hepatic necrosis; cholestatic jaundice; renal Fanconi syndrome; and excruciating, recurrent, porphyria-like neurologic pain crises. Caused by reduced heme synthesis, the pain crises typically occur following intercurrent illnesses, starting with irritability and progressing to severe pain; the child assumes a position of hyperextension of the trunk and neck. These painful crises may last from 1 day to as long as a week. Other children may develop weakness or paralysis, requiring ventilatory support. Autonomic dysfunction with ileus, hypertension, and tachycardia may occur. Neurologic crises, especially those with paralysis, have an associated mortality rate of 10%. It is believed that these crises are similar to what occurs in acute intermittent porphyria with decreased  $\delta$ -ALA dehydratase activity and accumulation of  $\delta$ -ALA in blood. Unfortunately, there is no absolute correlation between blood levels of  $\delta$ -ALA and clinical symptoms.

Early mortality, typically in the first decade, occurs due to liver failure, hepatocellular carcinoma, or neurologic crisis (66). At the other end of the severity continuum is a “chronic form,” with slower progression of growth failure, hepatic nodular cirrhosis, renal tubular acidosis with generalized aminoaciduria and hypophosphatemia,

and episodic neurologic crises. The hepatic nodules often contain regenerating hepatocytes with spontaneous reversion to the wild-type *FAH* genotype (67). Patients with the chronic form typically develop rickets and nephrocalcinosis due to hyperphosphaturia and have a high risk of developing hepatocellular carcinoma in childhood or adolescence.

The observed biochemical abnormalities include elevated urinary levels of succinylacetone, *p*-hydroxyphenyllactic, and *p*-hydroxyphenylacetic acids. Affected children have an increased concentration of tyrosine (two to three times normal) and methionine in the plasma owing to the reduced activity of pHPPA dioxygenase and methionine adenosyl transferase activity, respectively. Serum AFP increases over time as liver damage progresses.

Newborn screening programs have begun to adopt succinylacetone measurement from dried blood spots to screen for tyrosinemia I, especially because tyrosine levels were neither sensitive nor specific for the detection of the disease. Earlier reports indicate that succinylacetone is a much better marker; the New York state newborn screening program screened approximately 500,000 newborns over a 2-year period, identifying two newborns with the disorder, with three false-positives. In the two true-positive cases, it was noted that their initial tyrosine levels would not have been flagged as abnormal (68).

The prevalence of tyrosinemia I in most parts of the world is low. It occurs in higher frequency in the Scandinavian countries, apparently from genetic drift; a modest number of cases have been reported in Finland. The highest frequency is along the St. Lawrence Waterway in Canada, where one in 20 individuals is a carrier owing to founder effect. A single mutation in the *FAH* gene (IVS12+5G>A) accounts for 90% of the abnormal alleles within this population (69). This same mutation has been identified in patients from northern Europe. Other mutations are present in lower frequency, with some evidence for ethnic prevalence: c.1009G > A in Scandinavia, p.W262X in Finland, and p.D233V in Turkey (70).

Heterozygotes for tyrosinemia I are asymptomatic and have normal plasma amino acid levels and normal values of succinylacetone in the urine and blood. Heterozygote detection can be accomplished by assaying *FAH* activity in cultured skin fibroblasts, lymphocytes, or red blood cells (71), or by identifying the specific mutation in the family by molecular analysis. Prenatal diagnosis can be performed by molecular analysis if the mutations are known, by measurement of *FAH* activity in cultured amniotic fluid cells or chorionic villus cells (71), or by documentation of increased succinylacetone in the amniotic fluid. The existence of a pseudodeficiency allele for *FAH*, although rare, needs to be considered when using prenatal diagnosis or testing for carriers (72).

There exist three approaches in the management of children with hepatorenal tyrosinemia: (1) metabolic

inhibition of the proximal segment of the tyrosine catabolic pathway, (2) dietary intervention with the reduction of phenylalanine and tyrosine, and (3) liver transplantation.

The primary focus of treatment in infants identified via newborn screening should be on prompt initiation of 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC; nitisinone), a potent inhibitor of pHPPA dioxygenase. NTBC effectively creates an enzymatic block proximal to the *FAH* deficiency, abolishing the generation of toxic fumarylacetoacetate, maleylacetoacetate, and succinylacetone. Treatment with NTBC, at a dose of 1 mg/kg/day, results in an immediate reduction in AFP levels, improvement in  $\delta$ -ALA dehydratase activity, normalization of coagulation times and urinary succinylacetone levels, and prevention of neurologic crises (73). Transient thrombocytopenia and neutropenia may occur, and plasma tyrosine levels will increase to 400–700  $\mu$ M. Due to risk of corneal tyrosine crystallization with levels exceeding 500  $\mu$ M, similar to the process occurring in oculocutaneous tyrosinemia (see below), any treatment with NTBC must be paired with dietary restriction of phenylalanine and tyrosine to keep tyrosine levels below 400  $\mu$ M. While published data regarding long-term efficacy of combined NTBC and low phenylalanine/tyrosine diet are sparse, these studies indicate that the best predictors of symptom-free outcome are initiation of treatment prior to 6 months of age and normalization of AFP levels (74,75).

When NTBC and dietary phenylalanine and tyrosine restriction are instituted in children identified symptomatically, they demonstrate dramatic reversal of symptoms, improved hepatic and renal function, and prevention of neurologic crises. However, the risk of developing hepatic cirrhosis, nodules, and carcinoma is not completely eliminated, especially in children diagnosed and treated after their second birthday (75). Prior to the development of NTBC, dietary therapy alone was used, which improved the clinical symptoms but did not prevent progression of the disease; liver and renal involvement would worsen, with eventual hepatic failure or the development of hepatic carcinomas, or both.

Patients treated with NTBC and diet need to be monitored with frequent phenylalanine/tyrosine levels to ensure adequate natural protein intake while preventing corneal tyrosine precipitation. Periodic measurements of liver transaminases, prothrombin and partial thromboplastin times, urinary succinylacetone, AFP levels, and liver imaging are necessary to monitor treatment efficacy, liver synthetic function, and development of hepatocellular carcinoma. If the AFP does not decrease after initiating therapy or increases at a later time, the patient needs to be evaluated for hepatic malignancy and transplantation (76).

For children who develop hepatic failure or hepatocellular carcinoma, orthotopic liver transplantation is

the remaining treatment modality, as NTBC alone is not effective in these circumstances (76). Although liver transplantation in children is not benign, it has offered improved survival and reduced morbidity to patients undergoing the procedure. Donor selection, operative technique, postoperative care, and immunosuppressive regimens have been developed, which have significantly reduced the rate of perioperative complications. Liver transplantation for children with tyrosinemia type 1 reverses the symptoms associated with acute hepatic failure, neurologic decompensations, and renal dysfunction. However, ongoing excretion of succinylacetone post-transplant has been reported (77).

A great deal has been learned about the pathogenesis and potential therapies for tyrosinemia from the study of knockout mice. Succinylacetone can react with amino acid side chains, particularly lysine, to form stable adducts that interfere with protein function. In addition to  $\delta$ -ALA dehydratase, succinylacetone inhibits DNA ligase I, which may explain the chromosomal breakage observed in hepatocytes of patients with tyrosinemia and contribute to carcinogenesis (78). Fumarylacetoacetate appears to induce apoptosis (79). Hepatocytes expressing FAH can completely repopulate the liver of the FAH-deficient mouse when NTBC is withheld because of the selective growth advantage of normal cells (80). Perhaps of import for humans, even when treatment with NTBC was started prenatally, the mice still developed hepatocellular carcinoma (81).

### 92.2.3 Oculocutaneous Tyrosinemia

Oculocutaneous tyrosinemia (OMIM 276600) results from a deficiency of TAT, which catalyzes the transamination of tyrosine to pHPPA. It has also been called tyrosinemia II, TAT deficiency, and keratosis palmoplantaris with corneal dystrophy and by the eponym of the Richner-Hanhart syndrome.

A typical patient with this disorder presents after the first year of life with eye irritation or skin lesions. Ocular symptoms typically include photophobia, conjunctival redness, and pain. These changes occur due to the deposition of tyrosine crystals within the corneal stroma with subsequent erosions and scarring.

The skin lesions consist of blisters on the fingertips and the thenar eminences. These progress to form painful hyperkeratotic plaques that involve the entire surface of the palms and the soles of the feet. The major microscopic changes found on skin biopsies are not diagnostic of the condition but show hyperkeratosis, parakeratosis, and acanthosis.

Mental retardation has been a common theme in many reported patients, particularly in those from a single, isolated rural area. These early patients were reported to have approximately 40% incidence of developmental delay. It is unclear whether the neurologic symptoms are a true manifestation of oculocutaneous tyrosinemia or

whether the mental retardation has been the symptom that caused a biochemical derangement to be sought, causing an ascertainment bias.

Deficiency of TAT causes accumulation of tyrosine within the biologic fluids. Plasma tyrosine values have ranged from 400 to 3000  $\mu$ M when first diagnosed. Other amino acids in the blood are reportedly normal, with the possible exception of a mild elevation in phenylalanine levels. Urinalysis shows a marked increase in tyrosine excretion and, paradoxically, an increased excretion of pHPPA, *p*-hydroxyphenyllactate, and *p*-hydroxyphenylacetate. These latter compounds apparently arise by the ability of mitochondrial aspartate aminotransferase to convert tyrosine to pHPPA.

TAT is present solely in the cytoplasm of hepatocytes and is the rate-limiting enzyme of tyrosine degradation; its transcription is regulated by hormone treatment and diet. A number of mutations in TAT have been identified in oculocutaneous tyrosinemia (82).

The treatment of oculocutaneous tyrosinemia is aimed at reducing plasma tyrosine levels. If tyrosine levels can be reduced to approximately 500  $\mu$ M, symptoms should resolve. It has been suggested, from the evaluation of patients with oculocutaneous tyrosinemia, that a plasma level of 600  $\mu$ M is a reasonable goal (83); however, data from children treated for tyrosinemia I with NTBC would indicate that a level of less than 500  $\mu$ M offers greater protection from corneal symptoms. Commercial formulas that are low in phenylalanine and tyrosine are available. These formulas can be used to replace milk and other major protein sources in the diet and, when coupled with a vegetarian-style diet, are effective in reducing plasma tyrosine and in reversing ocular and skin symptoms.

### 92.2.4 Alkaptonuria

Alkaptonuria is a rare autosomal recessive disorder of homogentisic acid metabolism caused by a deficiency of homogentisic acid oxidase (84–86). Alkaptonuria is more frequent in Slovakia and the Dominican Republic (87). A number of mutations have been identified (88,89). Although rare, studies on alkaptonuria are of great historical significance in the field of metabolism and genetics. Sir Archibald Garrod developed his ideas of inherited metabolic disorders from his studies of alkaptonuria.

The presenting symptom of alkaptonuria is that of urine that turns dark brown or black on prolonged exposure to oxygen or rapidly after the addition of an alkali. Alkaptonuria is a genetic cause of ochronosis, in which a slate blue or gray pigmentation of the sclera of the eyes and the cartilage of the ears becomes evident by the second or third decade of life and cartilage becomes progressively black. Although the disorder is often diagnosed in childhood, it may not be detected until adulthood, when arthritis appears or dark pigmentation of the cartilage is

noted. In addition to arthritis, with progressing age, individuals with alkaptonuria frequently develop degenerative disk disease and back pain, aortic and mitral valve stenosis, coronary artery calcifications, nephrolithiasis, and tendons that tear easily (86).

Oxidation of homogentisic acid leads to formation of a pigmented polymer, the structure of which has not been elucidated. The pigment is preferentially deposited in the cartilage, leading to arthritis, mostly of the hip and knee, occurring earlier in men. There is degeneration and calcification of the intervertebral disks of the lumbar spine, followed by fusion. The radiographic appearance is nearly pathognomonic. The mechanism of damage to the cartilage is not known. Ochronosis also occurs in the cardiac valves, and there is a high percentage of alkaptonuric patients older than 50 years with aortic valve thickening, stenosis, and insufficiency (90). There is currently no cure for alkaptonuria. Some have advocated the consumption of up to 1 g of ascorbate per day to diminish pigment deposition in the cartilage by increasing renal excretion of homogentisic acid or its oxidized metabolite (87,91). However, this approach seems to have little clinical effect (86). NTBC (nitisinone), an inhibitor of pHPPA dioxygenase, decreases the production of homogentisic acid and has been proposed as a potential therapy but would probably require reduction of tyrosine intake in the diet similar to tyrosinemia type I (86).

### 92.2.5 Other Disorders of Tyrosine Metabolism

A number of other abnormalities of tyrosine metabolism have been reported but those are very rare, fail to cause disease in many homozygous individuals, or cause disease without obvious biochemical abnormalities. These disorders are noted here (for a more extensive discussion, see Reference (64)).

Deficiency of 4-hydroxyphenylpyruvate dioxygenase is associated with the condition known as tyrosinemia type III. Tyrosine levels are high in the blood, and 4-hydroxyphenylpyruvate, 4-hydroxyphenyllactate, and 4-hydroxyphenylacetate excretion is increased in the urine. It is unclear whether this biochemical abnormality results in disease or is associated with mental retardation (92).

Hawkinsinuria, named from the first family in whom it was described, is a disorder that leads to the accumulation of an intermediate in the tyrosine catabolic pathway. The exact enzymatic and genetic mechanism is not understood but is thought to be a defect in a partial reaction of the pHPPA dioxygenase reaction. The symptoms vary from none to severe acidosis and failure to thrive and may relate to the protein content of the diet. The condition responds to dietary protein limitation despite the absence of elevations in plasma tyrosine levels. It appears to become less threatening as the patient matures. The

mode of inheritance has not been identified, but it may be autosomal dominant (93).

## 92.3 DISORDERS OF GLYCINE METABOLISM

Glycine is the smallest and the most ubiquitous of the naturally occurring amino acids. It is not an essential amino acid in either infants or adults. Its major synthetic sources are probably through the one-carbon metabolic pathway and recovery from protein catabolism. Glycine may account for 25% of the composition of many proteins and is involved in the synthesis of creatine, glutathione, heme, and porphyrins. Glycine may also be used in the formation of glycogen and synthesis of purine.

The major reaction of glycine is its reversible conversion to serine, catalyzed by serine hydroxymethyltransferase (Figure 92-3). This enzyme requires tetrahydrofolate as a cofactor; the energetics favor the formation of glycine. An alternative and major route for the conversion of glycine to serine is through the glycine cleavage reaction. In this system, glycine reacts with tetrahydrofolate and is decarboxylated and deaminated to form N<sup>5,10</sup> methylenetetrahydrofolate, which is combined with a second molecule of glycine to form serine in a reaction catalyzed by serine hydroxymethyltransferase. The glycine cleavage system takes place only in the mitochondria by a complex four-protein system that is responsible for the decarboxylation. This four-protein system is similar in structure to the pyruvate-dehydrogenase complex and contains (1) a P-protein that is pyridoxal-dependent, the glycine decarboxylase; (2) an H-protein that is a hydrogen carrier protein, utilizing lipoic acid as a cofactor; (3) a T-protein that is required for binding of tetrahydrofolate; and (4) an L-protein that is lipoamide dehydrogenase. Mutational alterations in any of these four proteins can theoretically lead to the syndrome of nonketotic hyperglycinemia; mutations in three of the four have, in fact, been described. Disorders of glycine metabolism are reviewed by Hamosh and Johnston (94).

Disorders of metabolism resulting in hyperglycinemia were originally divided into two groups: ketotic and

**FIGURE 92-3** Abbreviated pathway for some of the metabolic reactions related to glycine. The known genetic defect is due to the deficiency of the (1) glycine cleavage complex causing nonketotic hyperglycinemia.

nonketotic. The term “ketotic hyperglycinemia” was coined by Childs and colleagues (95) to describe infants with metabolic acidosis, ketonuria, and hyperglycinemia. It was subsequently determined that children with this syndrome have disorders of organic acid metabolism, with secondary perturbations in glycine metabolism. These are principally children with propionic, methylmalonic, and isovaleric acidemia. These disorders are reviewed in Chapter 91. The recognition of nonketotic hyperglycinemia occurred in a group of children who typically present with severe neurologic symptoms soon after birth; absence of acidosis and organic acidemia; and elevated concentrations of glycine in plasma, CSF, and urine.

### 92.3.1 Glycine Encephalopathy

Glycine encephalopathy (OMIM 605899), classically known as nonketotic hyperglycinemias, represents several distinct genetic abnormalities that present with similar clinical findings (reviewed in Reference (94)). The estimated frequency of glycine encephalopathy is 1:12,000 to 63,000 live births (96). The classic infant with glycine encephalopathy appears normal at birth but soon develops poor feeding, listlessness, hypotonia, lethargy, respiratory failure, and seizures. While not specific for this disorder, burst-suppression pattern is usually seen on electroencephalography. Onset of symptoms typically occurs before 1 week of age and often in the first few days of life. The neurologic progression is inexorable, and these children develop intractable seizures, hypertonicity, and failure of intellectual development. Dysphagia leads to high risk of aspiration pneumonia. Most of these infants die of neurologic complications at younger than 1 month of age or, if they do survive, from infections before 2 years of age. Few live beyond this age and those who do demonstrate little to no cognitive development, require enteral feeding and have extremely refractory seizure disorders. Men may fare slightly better than women (97).

Rare cases of neonatal “transient nonketotic hyperglycinemia” have been described in which the intellectual outcome can be normal (98–100). There is currently no way to distinguish these rare babies from the much more common cases with an extremely poor outcome, making decisions about initiation or withdrawal of mechanical ventilation in the newborn period difficult (96).

Milder forms of glycine encephalopathy do exist. Some young children may present with mental retardation with slowly progressive neurologic features and seizures. Some families have had children who have a clinical course most similar to a neurodegenerative disease, with its onset between 6 months and 1 year of age. Still older persons have been described who present in adolescence with weakness and spasticity and whose condition may be confused with Friedreich’s ataxia or even Charcot-Marie-Tooth disease (101). However,

mutations in the glycine cleavage complex have not yet been demonstrated in these late-onset cases. The critical finding in establishing these individuals as having a form of glycine encephalopathy is dependent on documentation of elevated glycine in plasma and CSF. Plasma glycine levels are three to five times normal, whereas those in the CSF are increased 15–30 times, and the CSF to plasma glycine ratio is greater than 0.04 (102). Although elevated plasma glycine is invariant in older infants, it may sometimes be normal or near-normal soon after birth. Administration of valproate as an anticonvulsant may cause elevated glycine in plasma, serving to confuse the diagnosis.

The metabolic abnormality in glycine encephalopathy is a defect in the conversion of glycine to serine. The major route for this conversion is through the glycine cleavage reaction. Liver tissue from patients with the disorder is unable to cleave the C-1 of the glycine molecule to form carbon dioxide in the presence of tetrahydrofolate (103,104). Approximately 80% of cases of glycine encephalopathy are due to deficiency of glycine carboxylase (P-protein) (105,106), 10–15% of cases from aminoacyl protein (H-protein) deficiency (107,108), and the remainder of cases in the tetrahydrofolate-binding protein (T-protein) (109). No defect has yet been identified in the lipoamide dehydrogenase (L-protein).

No consistently effective treatment is available to reverse the neurologic damage that occurs in nonketotic hyperglycinemia. Low-protein diets, sodium benzoate, folic acid, and benzodiazepines have not proved effective (108). Strychnine has been given to a number of patients, with reports of improvement in muscle tone, but no improvement has been documented in their neurologic status (108). Some patients have partially responded to dextromethorphan (8–12 mg/kg/day) and high-dose sodium benzoate (500–600 mg/kg/day) (97). Dextromethorphan is a noncompetitive antagonist of the NMDA type of glutamate receptors, which may be stimulated by glycine (110).

Nonketotic hyperglycinemia is inherited as an autosomal recessive condition. Men and women are equally affected, and an increased incidence of consanguinity has been noted among parents. Genetic heterogeneity exists based on variation in clinical presentation and on known deficiencies of the P, H, and T enzymes of the glycine cleavage reaction. The glycine cleavage reaction is not detectable in normal white cells or fibroblasts, but it may be usefully studied in transformed lymphocytes (111). There is no detectable alteration in plasma glycine levels of obligate heterozygotes.

In patients with defined mutations, prenatal diagnosis may be carried out using molecular analysis of the gene from amniocytes or chorionic villi. The identification of a common p.S564L mutation in the P-protein in Finns and a p.H42R mutation in the T-protein in Israeli-Arabs makes prenatal diagnosis and heterozygote detection straightforward in these populations (112). Analysis of

Cystathionine is cleaved by  $\gamma$ -cystathionase to form cysteine and  $\alpha$ -ketobutyrate. Cystathionine is not known to function in other reactions. This enzyme also requires pyridoxal phosphate as a cofactor. Cysteine may undergo a number of enzymatic reactions. It is an important amino acid in proteins, playing a key role in folding and stabilization; as noted, it may be an essential or a conditionally essential amino acid in the neonate. It is a component of glutathione, a compound important in maintaining the redox state of the cell and in stabilizing the cell membranes. It also participates in the formation of coenzyme A and is metabolized to organic sulfate through sulfite. The final step is catalyzed by sulfite oxidase, a molybdenum-dependent enzyme.

Deficiency of  $\gamma$ -cystathionase produces cystathioninuria, an apparently benign autosomal recessive disorder. Deficiency of methionine adenosyltransferase causes hypermethioninemia, which can be inherited as an autosomal dominant or recessive trait. In the benign autosomal dominant form, mutations in one monomer of the homotetrameric enzyme interfere with function, resulting in moderate hypermethioninemia. Although most individuals are normal, patients with the autosomal recessive form due to functional null mutations have severe hypermethioninemia and may have demyelination in the brain and cognitive impairment (120).

The most common and important genetic defects of the sulfur amino acids produce an accumulation of homocysteine. Classified as the hyperhomocysteinemias, they are the result of enzymatic defects in either CBS (catabolic pathway) or the remethylation of homocysteine to methionine, encompassing disorders of folate and B<sub>12</sub> metabolism. Disorders causing elevations in urinary homocysteine are also termed homocystinuria, the most common cause of which is CBS deficiency.

### 92.4.1 CBS Deficiency

Before the recognition of homocystinuria due to CBS (OMIM 236200) deficiency as a defined entity, affected patients were confused with those with Marfan syndrome because of similarities in the clinical phenotype, including a thin habitus, scoliosis, pectus excavatum, dislocated lenses with myopia, and, occasionally, some degree of arachnodactyly. A significant number of patients have mental retardation. In 1962, and during the immediate years thereafter, homocystinuria was recognized as a discrete entity and the enzymatic defect defined (121). The separation of homocystinuria from Marfan syndrome represented one of the earliest and best clinical examples of the concept of phenocopies (122).

The classic description of the patient with homocystinuria is the young teenager who is tall and slender, and has scoliosis, long extremities, a high arched palate, light-colored dry hair, pale skin with livedo reticularis, and bilateral dislocation of lenses with myopia. Radiographs of the skeletal system demonstrate osteoporosis. A mild

to moderate degree of mental retardation may be present. This description undoubtedly represents the extreme clinical phenotype, because most patients with homocystinuria do not fit this classic description. It is striking that the disorder was first described in a more severely mentally retarded population, in which the classic phenotype was not noted.

Since the observation by Hooft and colleagues (123) that some patients with CBS deficiency may respond to pyridoxine (vitamin B<sub>6</sub>) therapy, two major subgroups have traditionally been defined: pyridoxine-responsive homocystinuria and pyridoxine-nonresponsive homocystinuria. The clinical manifestations of the two groups are different, with those who are pyridoxine-responsive tending to have a later onset, a milder phenotype and a better prognosis. Somewhat fewer than 50% of all patients with CBS deficiency respond to 25–500 mg of pyridoxine per day, with significant reduction in their plasma homocysteine concentration (117).

Ninety percent of patients with CBS deficiency have dislocated lenses; in these patients, 90% of lenses are dislocated downward in contrast to patients with Marfan syndrome, in whom the lenses typically dislocate upward. This may be observed in patients as young as 2 years. Half of the pyridoxine-nonresponsive patients have documented lens abnormalities by 6 years of age and half of the responsive patients have dislocation by 10 years of age. Myopia always accompanies lens subluxation, and occasionally, secondary glaucoma occurs. Retinal degeneration has been reported. Lens dislocation occurs because of a disruption of the zonular fibrils, which are predominantly composed of fibrillin-1 (mutated in Marfan syndrome), a cysteine-rich protein. Homocysteine may bind the cysteine residues in fibrillin-1, disturbing proper microfibril formation.

Mental retardation is a frequent observation in affected patients. The median IQ for pyridoxine-responsive patients has been estimated at 78, with 22% having IQs greater than 90, as compared with pyridoxine-nonresponsive patients, with a mean of 56 and only 4% with IQs greater than 90. Abnormal electroencephalograms (EEGs) and seizures are occasionally noted, and there is an impression of significant psychiatric disturbances in approximately one-half of the patients. Personality and behavior disorders tend to predominate in the pyridoxine-nonresponsive group. Rare cases have developed leukodystrophy with spasticity or an extrapyramidal movement disorder. When treatment is initiated early (such as in patients detected by newborn screening) in pyridoxine-responsive patients, the intellectual outcome is normal or near-normal (117).

Pancreatitis in CBS deficiency has been reported (124). In addition, spontaneous pneumothorax (125), which not coincidentally is a complication of Marfan syndrome, also occur in the disorder. Homocysteine inhibits tyrosinase, potentially explaining the hypopigmentation that patients frequently have (126).

Osteoporosis can usually be documented by age 20 in at least 50% of patients. It has been suggested that the osteoporosis may be a contributing cause in patients in whom scoliosis develops and is certainly contributory to those patients who demonstrate vertebral collapse. Homocysteine appears to interfere with collagen cross-linking (127).

The major life-threatening symptom in patients with classic homocystinuria is the propensity toward vascular thrombosis. Twenty-five percent of untreated patients would have had a thromboembolic event by the age of 20, earlier in pyridoxine-nonresponsive cases. Mudd and colleagues (117) have estimated that the risk of a significant thromboembolic event in a young adult with untreated homocystinuria is approximately 4% per year. The arterial walls show marked fibrous intimal thickening and abnormalities of the media. In vitro, homocysteine stimulates smooth muscle cell proliferation (128). In addition to the arterial vascular changes, homocysteine causes hypercoagulability. There is an increased risk of thromboembolism if there are further genetic risk factors, such as factor V Leiden, a common form of activated protein C resistance (129).

Patients may be suspected of having homocystinuria on the basis of clinical phenotype, the presence of dislocated lenses in a child, or the occurrence of a thromboembolic phenomenon in a child or young adult. Some cases are detected as a consequence of metabolic evaluation in a retarded individual. Homocystine in the urine is easily detected by an amino acid analysis. In the plasma, methionine is elevated in the range of 500–2000  $\mu\text{M}$  and homocysteine in the range of 50–200  $\mu\text{M}$ . The documentation of elevated methionine concentration in plasma is necessary for the presumptive diagnosis of CBS deficiency in the absence of a direct enzymatic assay; molecular genetic sequencing is used to confirm the disorder.

CBS deficiency must be distinguished from other defects that can cause homocystinuria, including problems in remethylation to methionine, a deficiency of  $N^5$ -methyltetrahydrofolate:homocystine methyltransferase, a deficiency of  $N^5$ , $^{10}$ -methylene tetrahydrofolate reductase, or a defect in cobalamin metabolism that results in a deficiency of methylcobalamin. These latter disorders typically have low or low-normal plasma levels of methionine. Homocystine is also seen in the urine of some patients with cystathioninuria owing to bacterial contamination and the synthesis of homocysteine from cystathionine. By contrast, some patients who have homocystinuria may be missed by urinary screening if they have been taking vitamin supplements containing pyridoxine.

Therapy is available for patients with CBS deficiency. In 25–50% of patients, homocysteine concentration in blood can be lowered to a significant degree by taking an oral dose of pyridoxine (50–500 mg/day). Lowering the plasma homocysteine concentration may offer considerable protection to most of these patients from

thromboembolic events. The clinical data suggest that patients with the lowest levels of plasma homocysteine would have the lowest incidence of thrombotic episodes. Folic acid depletion has been noted in a number of patients with CBS deficiency, and it is supplemented routinely (1000  $\mu\text{g/day}$ ) along with pyridoxine. This phenomenon may relate to the ability to recycle homocysteine to methionine, a reaction that is both vitamin  $B_{12}$ - and folate-dependent. Betaine (up to 150 mg/kg/day) promotes the remethylation of homocysteine to methionine, a far less toxic or perhaps nontoxic compound, and therefore is used to lower homocysteine levels still further.

A low-methionine diet has been used to prevent the accumulation of homocysteine. This approach is most effective when used in young infants found to have homocystinuria through newborn screening programs or early diagnosis. Patients identified later on are rarely able to assume this degree of discipline. Special low-methionine formulas are available for dietary management. These formulas are supplemented with a small amount of milk and L-cysteine to meet the methionine and L-cysteine requirements and to maintain plasma methionine levels to a near-normal range. Preliminary evidence indicates that methionine-restricted diets are beneficial to children who are non-pyridoxine-responsive.

To assist in the prevention of thromboembolism in patients who have persistent homocystinemia, dipyridamole combined with aspirin is recommended. Although short of unequivocal statistical proof, the prevailing impression is that these drugs are helpful. Because of the increased risk of thromboembolism, estrogen-containing oral contraceptives are probably best avoided. Pregnancy, or surgical procedures conducted with adequate hydration do not appear to significantly increase the risk of complications. Although there may be an increased rate of fetal loss, the offspring of homocystinuric women appear to be normal.

Deficiency of CBS is inherited as an autosomal recessive condition. The estimated incidence varies from one in 50,000 to one in 400,000, with the highest incidence in Italy and Ireland. More than 158 different mutations in CBS have been described, with most being quite rare (141; <http://cbs.lf1.cuni.cz/mutations.php>). The p.G307S substitution is most common in the Irish and results in a pyridoxine-nonresponsive phenotype, whereas the p.I278T mutation is the most common in Italians and confers pyridoxine responsiveness. These two mutations may represent up to 50% of those seen in some populations of northern European origin (130). Other recurrent mutations that predict pyridoxine responsiveness when found in the homozygous state include p.A114V, p.R266K, and p.R336H. Recurrent mutations predicting nonresponsiveness when found in the homozygous state are p.T191M and p.C165Y (116).

Most newborn screening programs for homocystinuria screen for hypermethioninemia. However, this

strategy results in most cases of pyridoxine-responsive CBS deficiency being missed (131). Homozygotes for the p.I278T mutation usually present with thromboembolic events in their third decade, and while they have elevated plasma homocysteine levels, they often have normal intelligence and absent ocular/skeletal symptoms (132). In countries like Ireland, where most cases are pyridoxine-nonresponsive and the incidence is 1:65,000, newborn screening can be quite effective (133).

Obligate heterozygotes have been documented to have less than normal activity when CBS activity has been measured in extracts of cultured fibroblasts, stimulated lymphocytes, long-term cultured lymphocytes, and liver tissue. In general, this activity has been less than 50% of the mean control specific activity observed in each tissue. It has been implied that the decrease in activity below 50% of normal is due to impaired activity of hybrid molecules, when the normal subunits of the enzyme are combined with mutant ones (dominant negative effect). Because of the rarity of the mutant gene in the population and the wide variation in normal enzymatic activity, it is difficult to reliably distinguish heterozygotes. Similarly, methionine loading followed by sensitive measurements of total homocysteine will not detect many obligate heterozygotes. Obligate heterozygotes may not have a significantly increased risk for vascular thrombosis, although a small increase in risk cannot be excluded with the available data.

Prenatal diagnosis of CBS deficiency is feasible by molecular analysis or enzymatic assay of cultured amniotic fluid or chorionic villus cells. CBS-deficient mice have been generated. The homozygotes die within 5 weeks. The heterozygotes have a twofold elevation in total homocysteine (134).

### 92.4.2 $N^{5,10}$ -methylenetetrahydrofolate Reductase Deficiency

The active cofactor necessary for the conversion of homocysteine to L-methionine is  $N^5$ -methyltetrahydrofolate. This cofactor is resynthesized from  $N^{5,10}$ -methylenetetrahydrofolate by the enzyme  $N^{5,10}$ -methylenetetrahydrofolate reductase (MTHFR). A small number of children have been reported with a deficiency of this enzyme (OMIM 236250). Patients deficient in the synthesis of  $N^{5,10}$ -methylenetetrahydrofolate accumulate homocysteine and have low or low-normal plasma methionine levels (135).

Affected patients show a spectrum of clinical symptoms. Young infants have been identified with severe neurological symptoms of hypotonia, poor feeding, failure to thrive, seizures, lack of neurocognitive development, and severe apnea. Most have died at younger than 1 year of age due to central respiratory failure. Several infants have responded well to high-protein intake, with or without supplementation with methyl-donor medications such as folinic acid and betaine. Older children

have been identified with MTHFR deficiency after presenting to medical attention for mental retardation, acute psychosis, muscle weakness, ataxia, marfanoid habitus, spastic paraparesis, or thromboembolic events (136). Adults have presented with gait disturbance. Some have shown improvement in symptoms when supplemented with pharmacologic doses of folate.

The disorder is inherited as an autosomal recessive condition. There is evidence that obligate heterozygotes can be distinguished by measurement of the enzymatic activity. Prenatal diagnosis has been accomplished. A number of mutations have been identified in these cases, and there is reasonable correlation between residual enzyme activity and clinical severity (135). However, there can be substantial variability within families, with one asymptomatic adult sibling of an affected patient having been reported (137).

### 92.4.3 Thermolabile $N^{5,10}$ -methylenetetrahydrofolate Reductase and Mild Homocysteinemia

Very little homocysteine exists in an unbound form in the blood. Between 70 and 80% of homocysteine is protein-bound, whereas the rest exists as homocysteine (homocysteine homodimer) and mixed disulfides. The most practical measurement to make is that of total homocysteine, requiring prior reduction of disulfide bonds. The 95th percentile in normal individuals for plasma total homocysteine is approximately 15  $\mu\text{mol/L}$ . Women have a lower homocysteine level than men, and the level increases with age, decreased vitamin intake, and decreased glomerular filtration rate (138).

Epidemiologic studies have shown that elevated homocysteine is associated with an increase in atherosclerosis, coronary artery disease, cerebrovascular disease, and venous thromboembolism. The exact mechanisms are not understood, but the available evidence suggests increased endothelial damage, oxidation of lipids, and proliferation of smooth muscle cells (139). It has been estimated that a 5  $\mu\text{M/L}$  increase in homocysteine confers the same risk for coronary artery disease as a 20 mg/dL increase in cholesterol—a 1.5-fold increase in the risk for coronary artery disease and cerebrovascular disease (140). Just as in CBS deficiency, the risk of thromboembolism due to mild homocystinuria is increased with other risk factors, such as activated protein C resistance due to the factor V Leiden mutation (141).

On a population basis, there is an inverse relation between folate intake and total homocysteine. There is lesser relationship between homocysteine and vitamin B<sub>6</sub> or B<sub>12</sub> intake. Folate and vitamin B<sub>12</sub> lower fasting homocysteine levels, whereas vitamin B<sub>6</sub> lowers the homocysteine level after a methionine load. Elevated fasting and post-methionine load homocysteine levels are independently associated with vascular disease (142);

thus, either measurement alone is insufficient to evaluate for hyperhomocysteinemia.

Most folate-responsive mild homocysteinemia is due to homozygosity for a common C677T polymorphism in methylene tetrahydrofolate reductase that produces a thermolabile enzyme (tMTHFR). Approximately 10% of European Caucasians are homozygous for tMTHFR. The enzyme tMTHFR has been epidemiologically associated with an increased risk for coronary artery and peripheral vascular disease (143–147). The only potential benefits of tMTHFR to those who carry it is that it may reduce the risk of acute lymphocytic leukemia (148) and colorectal cancer (149).

Maternal folate deficiency is clearly associated with fetal neural tube and cardiac defects, but the role of homocysteine in the pathogenesis of these birth defects is not clear (150). There is mounting evidence that elevated homocysteine may be teratogenic. Because of differing genetic backgrounds and amounts of folate intake in different studies, it is difficult to compare the often contradictory epidemiologic studies. In any case, it is doubtful that the full effects of folate supplementation on the reduction of neural tube defects can be explained solely on the basis of reduction of homocysteine levels. In chick embryos, administration of homocysteine causes neural tube and cardiac defects that are preventable by adding folate (151). In humans, homozygosity for tMTHFR in the fetus is associated with an increased risk for neural tube defects when the maternal folate intake is low (152). Increased maternal homocysteine may also confer an increased risk for congenital heart disease (153) and placental abruption (10,154). The tMTHFR homozygosity may be associated with an increased risk of cleft palate (155) but not cleft lip +/- cleft palate (156).

Regardless of the mechanism of action in the prevention of birth defects or the exact risk for vascular disease associated with mild homocysteinemia, consumption of adequate folate appears prudent for all ages. The exact daily requirement of folate to prevent homocysteinemia is not known, but 0.4 mg/day has been adequate in most studies. This dose is too small to exacerbate the neurologic symptoms of vitamin B<sub>12</sub> deficiency, which is the major fear impeding full folate supplementation of food in the United States (157).

#### 92.4.4 Homocystinuria due to a Deficiency of Methylcobalamin

Vitamin B<sub>12</sub> is an essential vitamin in humans. A complex series of transport and conversion reactions are required to produce biologically active forms. In the small intestine, ingested hydroxycobalamin is bound to intrinsic factor and transported into the enterocyte. It is released into the portal circulation bound to transcobalamin II. This complex interacts with a specific receptor on the cell surface and is endocytosed. The endocytic vesicles fuse with the lysosome, and the binding proteins

are hydrolyzed. Hydroxycobalamin undergoes mediated transport from the lysosome into the cytosol. In the cytosol, it is either converted to methylcobalamin or transported into the mitochondria, where it is reduced and adenylated to form adenosylcobalamin.

Methylcobalamin is the active cofactor for the conversion of homocysteine to L-methionine by the enzyme N<sup>5</sup>-methyltetrahydrofolate:homocysteine methyltransferase, also known as methionine synthase. A deficiency of methylcobalamin, by any number of mechanisms, can result in homocystinuria, homocystinemia, hypomethioninemia, and significant clinical symptoms. Adenosylcobalamin is an essential cofactor for methylmalonyl-CoA mutase, the enzyme deficient in typical methylmalonic acidemia (see Chapter 97). Isolated deficiency of adenosylcobalamin synthesis produces methylmalonic acidemia. Combined deficiencies of both methylcobalamin and adenosylcobalamin metabolism produce disorders, with elevations in homocysteine and methylmalonic acid, although the biochemical abnormalities are less severe than those in CBS or methylmalonyl-CoA mutase deficiency.

Precellular defects, such as intestinal malabsorption of cobalamin and severe transcobalamin II deficiency, are clinically milder than those of intracellular cobalamin metabolism. Affected individuals usually have megaloblastic anemia, developmental delay, or failure to thrive. Defects in the intracellular cobalamin pathway are designated by their complementation group (Cbl A through G) and are inherited as autosomal recessive traits. Cbl A and B cause isolated deficiency of adenosylcobalamin synthesis and consequently methylmalonic acidemia without hyperhomocysteinemia (see Chapter 97).

The Cbl G defect (OMIM 250940) is due to a deficiency of methionine synthase, which uses N<sup>5</sup>-methyltetrahydrofolate as a methyl donor to create methionine from homocysteine (158). For methionine synthase to remain active, its cobalamin core must remain in the reduced cob(I)alamin state. However, at physiologic conditions, the cobalt core will spontaneously oxidize to the cob(II)alamin state. To regenerate the active enzyme, the methionine synthase reductase enzyme utilizes S-adenosylmethionine to reduce methionine synthase back to the +1 oxidation state and remethylate the enzyme. A deficiency of methionine synthase reductase results in the Cbl E defect (OMIM 236270) (159). Clinically, both disorders typically present in the same way, with developmental delay, hypotonia, ataxia, cerebral atrophy, seizures, thromboembolic events, nystagmus, or blindness in the first several years of life. One patient with Cbl G defect presented in adulthood and was initially misdiagnosed as a case of multiple sclerosis (160). Biochemically, patients with Cbl E and G defects have megaloblastic anemia, elevated plasma total homocysteine and hypomethioninemia without methylmalonic aciduria. Therapy with intramuscular hydroxocobalamin (minimum 1000 µg/day) and oral folic acid (1000 µg/day), betaine (up to 250 mg/kg/day), and L-methionine

is able to correct anemia, reduce plasma homocysteine levels and normalize plasma methionine, but often times, the patients remain developmentally delayed. Early diagnosis and initiation of treatment, even prenatally, may help prevent irreversible neurologic damage (119,161).

Patients with Cbl C (OMIM 277400), Cbl D (OMIM 277410), and Cbl F (OMIM 277380) defects are unable to convert hydroxycobalamin to either methylcobalamin or adenosylcobalamin, leading to combined homocysteinemia and methylmalonic acidemia. Cbl C defect is the most common inborn error of cobalamin metabolism. Most patients are now identified by newborn screening, typically with elevated C3-acylcarnitine and C3:C2 ratio. Confirmatory testing will show elevated plasma total homocysteine, methylmalonic acid, and propionylcarnitine levels; normal vitamin B<sub>12</sub> levels; and hypomethioninemia. Plasma-free carnitine levels may also be depleted. It is important to note that there are Cbl C cases, even severe ones, that have not been detected by newborn screening, so the disorder must be suspected in any neonate with lethargy, poor feeding, or failure to thrive. Older children will present symptomatically with developmental delay, hypotonia, or seizure disorder; nystagmus, reduced visual acuity, gait disturbance, myelopathy and psychosis have also been described as presenting symptoms (119,162). Megaloblastic anemia or pancytopenia is usually present as well. Additional findings may include congenital heart disease, cerebral atrophy, hydrocephalus, and renal failure (163). Patients may have dysmorphic features (164). Treatment with intramuscular injections of hydroxocobalamin (1000 µg/day, although doses as high as 20,000 µg/day have been utilized (165)), betaine, and folic acid can normalize levels of methionine and reduce hyperhomocysteinemia and methylmalonic acidemia. A low propiogenic amino acid diet and levocarnitine supplementation may also be used to mitigate the toxic effects of methylmalonic acid. Response to treatment is variable. Patients with milder disease typically have normalized levels of homocysteine and methylmalonic acid, and those treated from birth often have normal growth and development. Biochemical analytes in patients with severe Cbl C defect will improve following treatment, but even those identified by newborn screening and treated immediately will manifest developmental delay, nystagmus, and seizures. Those who are identified and treated later in childhood do improve but are neurologically impaired; neurologic deterioration can occur in spite of therapy (163,166).

The Cbl C defect is caused by recessive mutations in the *MMACHC* gene; the protein product appears to encode an enzyme that removes the axial cyano group from exogenous cobalamin and may be involved in its trafficking as well. Recurrent mutations observed in *MMACHC* include the “European” c.271dupA frameshift-premature truncation, whose haplotype was observed in many ethnicities; the c.331C > T “Acadian” mutation; the c.394C > T “East Indian/Middle Eastern”

nonsense mutation; and the c.328\_331delAACC frameshifting deletion, very common in Mexican and Central American countries (167).

There have been 10 patients reported with Cbl D defect. Encoded by the *MMADHC* gene, the Cbl D protein appears to be a homolog of an ATPase portion of an ABC transporter. The biochemical phenotype is variable and dependent on the site of the mutation; three patients termed “Cbl D variant 2” demonstrated isolated methylmalonic acidemia and had mutations affecting the N-terminal portion of the protein; three patients termed “Cbl D variant 1” had isolated hyperhomocysteinemia, with mutations at the C-terminal end; and four “classic” patients had elevations in both methylmalonic acid and homocysteine bore mutations, resulting in a nonfunctional protein. Based on these observations, the putative function of the Cbl D N-terminal domain is to assist in adenosylcobalamin synthesis and that of the C-terminal domain to assist in methylcobalamin synthesis (168). Regardless of the biochemical derangements, the symptoms of Cbl D deficiency are significant: seizures, developmental delay, and encephalopathy were reported from all three variants; visual disturbances and megaloblastic anemia were observed in the classic and variant 1 forms. One patient was described as having “poor social skills and behavioral problems,” while another presented with acute psychosis. The classic form and variant 1 have been treated with intramuscular hydroxycobalamin, betaine, aspirin, and folic acid, with biochemical improvement, although one neonate died following a thrombotic event. Hydroxocobalamin and levocarnitine have been used for variant 2.

The Cbl F defect arises from deficient efflux of cobalamin out of the lysosome following hydrolysis from transcobalamin II. Multipoint linkage analysis of 12 patients with Cbl F defect led to the identification of *LMBD1*, a lysosomal transmembrane protein, as the protein deficient in Cbl F. Common presenting symptoms of patients with Cbl F defect were prenatal-onset growth retardation with postnatal failure to thrive, stomatitis, feeding difficulties, developmental delay, and cardiac abnormalities. Three of the 12 patients were identified from newborn screening with elevated propionylcarnitine in newborn blood spots. Following treatment with intramuscular hydroxocobalamin, three patients were completely asymptomatic. Only one of these three patients was identified from newborn screening. Death in two patients following cardiac surgery, and in one hydroxycobalamin-treated patient from sudden unknown causes, was observed. Ongoing issues faced by survivors were short stature, developmental delay, and poor attention span (169).

#### 92.4.5 Sulfite Oxidase Deficiency

Sulfite oxidase (see Figure 92-4) deficiency is a rare neurodegenerative disorder, typically presenting during

the neonatal period (170,171). Infants initially may have only feeding difficulties, but they rapidly develop abnormal tone, severe irritability, and refractory generalized and myoclonic seizures. Ectopia lentis, similar to that seen in patients with homocystinuria, may be present at birth but is often evident only after several months. The brain rapidly becomes atrophic, secondary to spongy degeneration and gliosis. Most of these children succumb in early infancy, but a few have survived several years, with severe neurologic impairment. One milder case has been reported, with an initial presentation at 17 months, owing to an incomplete enzymatic defect (172). The urine of the affected individuals contains increased quantities of sulfite, thiosulfate, and *S*-sulfocysteine, whereas the sulfate content is markedly diminished. Sulfite oxidase deficiency is an autosomal recessive disorder with genetic heterogeneity. Although a handful of cases of isolated sulfite oxidase deficiency (OMIM 272300) due to a defect in the apoenzyme have been identified, the majority of cases have been attributed to a deficiency of a novel molybdenum-containing pterin cofactor (OMIM 252150). The molybdenum cofactor is also required for the activities of xanthine oxidase and aldehyde oxidase. Molybdenum cofactor deficiency itself displays locus heterogeneity, with recessive mutations described in *MOCS1*, *MOCS2*, *MOCS3*, or *GEPH* genes, resulting in the disorder (173,174) (Figure 92-5). Prenatal diagnosis can be performed with sequencing of known mutations in the causative gene or with biochemical assays from chorionic villi (175).

Clinically, patients with molybdenum cofactor deficiency are identical to those with isolated sulfite oxidase deficiency, except for hypouricemia and xanthinuria that may result in renal calculi. In addition, urothione, a precursor of the pterin moiety, is undetectable in the urine. The pathogenesis of sulfite oxidase deficiency is unclear; a deficiency of sulfate could disturb the synthesis of sulfated glycosaminoglycans. However, sulfite, normally present only in small quantities, is a highly reactive compound. Modification of the sulfhydryl group of cysteine residues, for example, could prevent normal protein cross-linking, similar to a hypothesized effect of homocysteine.

Treatment in one patient with *MOCS1* deficiency utilizing daily intravenous infusions of cyclic pyranopterin monophosphate (cPMP, 80–160 g/kg) to bypass the enzymatic block resulted in near-normalization of markers related to sulfite oxidase (sulfite, *S*-sulfocysteine, and thiosulfate) and xanthine oxidase deficiency (xanthine and uric acid) within a week and a marked reduction of seizures within 2 weeks. At the last reported follow-up, the patient was free of seizures and thriving but developmentally delayed, with spastic quadriplegia and hyper-tonicity. Her brain magnetic resonance imaging (MRI) demonstrated cerebral atrophy and had the characteristic cystic appearance. Because the patient demonstrated these abnormalities prior to treatment, the authors suggested that earlier recognition by newborn screening and initiation of cPMP would lead to improved developmental

**FIGURE 92-5** Diagram for the synthesis of the molybdenum cofactor from GTP. Genetic defects in *MOCS1* result in MoCD type A, which mechanistically is the only subtype amenable to cPMP treatment. Mutations in *MOCS2* and *MOCS3* give rise to MoCD type B, and mutations in *GEPH* are responsible for MoCD type C. (Used with permission from Reiss, J.; Hahnewald, R. Molybdenum Cofactor Deficiency: Mutations in *GPHN*, *MOCS1*, and *MOCS2*. Hum. Mutat. 2011, 32, 10–18.)

outcomes in *MOCS1*-deficient patients. Larger-scale clinical trials of cPMP are underway (176,177).

## 92.5 DISORDERS OF THE BCAAS

Leucine, isoleucine, and valine are essential amino acids in humans. Each is required for normal nutrition and growth in children and to maintain protein synthesis in adulthood. The term “branched chain” is designated to these amino acids because of their chemical structure; each contains a methyl group that branches from the main aliphatic carbon chain. As a group, they play an important regulatory role in body nitrogen, carbohydrate, and ketone body homeostasis, but their fate is to be used primarily for protein synthesis; the quantity of amino acids not used for protein synthesis undergoes a series of irreversible oxidative steps to form organic acids that eventually enter the tricarboxylic acid cycle or are used for gluconeogenesis.

**FIGURE 92-6** Abbreviated pathway for the metabolism of the BCAAs. The known enzyme defect affecting the amino acid metabolism is (1) branched-chain ketoacid dehydrogenase, causing MSUD.

Two major groups of clinical disorders are associated with deficiencies in the steps of BCAA metabolism. One group of disorders leads to the accumulation of one or more amino acids and includes, primarily, maple syrup urine disease (MSUD) (reviewed in References (178,179)). Disorders more distal in the catabolic pathway are associated with the accumulation of organic acids and are termed “the organic acidemias” (see Chapter 97). The most common disorders of organic acid metabolism include (1) isovaleric acidemia, (2) methylmalonic acidemia, and (3) propionic acidemia. A significant number of other organic acidemias exist within this catabolic pathway; this group is reviewed in Chapter 97.

### 92.5.1 Maple Syrup Urine Disease

The steps in the metabolism of leucine, isoleucine, and valine are similar (Figure 92-6). There is an initial cytosolic transamination reaction, with  $\alpha$ -ketoglutarate serving as the amino group acceptor, forming, respectively, 2-oxoisocaproic acid, 2-oxo-3-methylvaleric acid, and 2-oxoisovaleric acid. The three 2-oxoacids then enter the mitochondrion via a common transporter.

The second reaction is an oxidative decarboxylation of the branched-chain  $\alpha$ -ketoacids. It is likely from biochemical data and from the *in vitro* study of human mutations that a single branched-chain dehydrogenase is used by the branched-chain 2-oxoacids for the reaction. Branched-chain ketoacid dehydrogenase is a large multienzyme complex similar in both structure and reaction mechanism to the pyruvate and  $\alpha$ -ketoglutarate dehydrogenases. It is located on the outer face of the inner mitochondrial membrane. It consists of four separate proteins:  $E_1\alpha$  and  $E_1\beta$ , which form a decarboxylase; a transacylase ( $E_2$ ); and a lipoamide oxidoreductase ( $E_3$ ). The  $E_3$  subunit of this complex is the same protein that forms a part of the pyruvate and  $\alpha$ -ketoglutarate dehydrogenase complexes.

The decarboxylase component requires, and is stabilized by, thiamine. Maximum activity of the entire

complex is dependent on lipoic acid, flavin adenine dinucleotide, nicotinamide adenine dinucleotide (NAD), and coenzyme A. The decarboxylase is carefully regulated by the opposing actions of a specific kinase and phosphatase. The kinase phosphorylates the  $E_1\alpha$ -subunit, inactivating the complex, and is itself inhibited by the precursors of the reaction (branched-chain  $\alpha$ -ketoacids); it is reversed by the action of the phosphatase, which is inhibited by the products of decarboxylation, as well as by a specific inhibitor protein. The complexity of the enzyme system allows at least seven separate proteins from different genetic loci to affect the integrity of the entire complex. The potential exists for many mutational events to affect the activity of this reaction.

A genetic deficiency of the activity of the dehydrogenase complex prevents further oxidation of the  $\alpha$ -ketoacids formed from their respective amino acids. This deficiency is responsible for the clinical syndrome of MSUD (OMIM 248600), one of the earliest described and best known of inborn errors of amino acid metabolism (180). Affected persons accumulate 2-oxoisocaproic acid, 2-oxo-3-methylvaleric acid, and 2-oxoisovaleric acid. These  $\alpha$ -ketoacids may be reversibly reaminated by transamination to again form their respective BCAAs. Thus, patients with a dehydrogenase deficiency accumulate the branched-chain  $\alpha$ -ketoacids along with the amino acids leucine, isoleucine, allo-isoleucine, and valine.

There is a continuum of clinical heterogeneity for MSUD, varying from the severe classic form to rather mild forms of the illnesses. The degree of severity would be related to the residual enzymatic activity of the dehydrogenase complex that exists under physiologic conditions for the substrates. Infants affected with the classic form of MSUD appear normal at birth but begin to have symptoms that occur within the first few days or weeks of life, possibly prior to notification of abnormal newborn screening results. These symptoms are associated with severe acidosis from buildup of 2-oxoacids; as valine and isoleucine are carbon sources for gluconeogenesis, hypoglycemia occurs because the enzymatic block compromises generation of gluconeogenic precursors.

Symptomatic infants soon demonstrate neurologic deterioration manifesting as flaccidity, a high-pitched cry, hypertonicity, and opisthotonic posturing. Cerebral edema is often clinically apparent and may be demonstrable, along with abnormal T2-weighted enhancement of the basal ganglia, on imaging studies during an acute episode (181). The odor of maple syrup can usually be detected in the urine, scalp, cerumen, and skin of the affected infants. Many such infants fail to survive the newborn period, and those who do survive usually demonstrate residual neurologic damage. Those in whom the onset is more indolent may have symptoms of poor feeding, vomiting, lethargy, ataxia, coma, and seizures. The prognosis for these individuals is improved if treated appropriately.

In addition to the classic form of MSUD, there are more mildly affected cases. Children with an intermediate form have ataxia, failure to thrive, and retarded development. Those with the intermittent form may present, even in adulthood, with episodes of ataxia and ketoacidosis, often brought on by intercurrent infections or excessive protein intake. A few patients have been identified with a thiamine-responsive variant, demonstrating improvement in the clinical course and increased (but still subnormal) tolerance for protein, when treated with pharmacologic doses of thiamine. Individuals ingesting fenugreek as a tea or spice may emit a maple syrup-like odor, causing great alarm, but this is a harmless phenomenon (182).

The diagnosis of patients with the classic form of MSUD is not difficult. When symptomatic as infants, these patients have an abnormal urine organic acid chromatogram quite characteristic of the disorder and containing high levels of the accumulated 2-oxoacids. Quantification of amino acids in plasma documents the marked increase in leucine, isoleucine, and valine, and the presence of allo-isoleucine. Allo-isoleucine in plasma may be considered almost pathognomonic of MSUD, appearing rarely in severe ketosis. This unusual amino acid is a diastereomer of isoleucine at the  $\beta$ -carbon, formed from keto-enol tautomerization of 2-oxo-3-methylvalerate that randomizes the  $\beta$ -carbon chirality.

The milder forms of MSUD may require a higher index of suspicion to diagnose, especially because they may not be detected by newborn screening methods utilizing only measurement of BCAAs (183). Patients with “intermittent MSUD” may only be clinically ill when affected with an intercurrent viral illness or when exposed to a high-protein intake. At such times, they may have symptoms of nausea, vomiting, lethargy, ataxia, and mild acidosis. Some of these patients show a persistent elevation of BCAAs and the presence of allo-isoleucine in their plasma; others may only demonstrate these changes when ill. Most only excrete abnormal quantities of 2-oxoacids when clinically symptomatic.

Management of a child with the classic form of MSUD can be frustrating. Many of these children either have

died as infants or have significant neurologic and intellectual impairment, despite special dietary intervention. Those who survive the neonatal period typically have an IQ averaging 70. Those with less severe decompensations generally have better outcomes, as do patients with milder forms (184,185). If aggressive management is started in the first few days of life, the outcome can be much better (186). Practically speaking, this requires prenatal diagnosis or newborn screening, with a short time from testing to referral for care.

Patients with MSUD tend to do well between acute intercurrent illnesses but are vulnerable to rapid deterioration when any situation arises, causing them to become anorexic and dehydrated, or are subjected to severe endogenous protein catabolism. The onset of an acute febrile illness is hazardous; the patient who cannot sustain oral intake with high-carbohydrate fluids, has a diminished state of consciousness, or both must be brought immediately to the hospital for intravenous or nasogastric nutritional support.

Therapy for the acute presentation or for acute deterioration involves the exclusion of exogenous sources of protein and high-glucose and high-calorie intravenous solutions to minimize the hypoglycemic drive to protein catabolism. Hemodialysis, continuous venovenous hemodialysis, continuous hemofiltration, or peritoneal dialysis may be necessary to remove very high levels of leucine, which is toxic to the CNS and well reabsorbed by the kidneys (187). To reduce fatigue and work of breathing, mechanical ventilation should be initiated if severe metabolic acidosis is present. Early readdition to the diet of the 17 nonbranched-chain amino acids may hasten protein synthesis and the return of the offending amino acids toward normal levels. For those with prolonged restriction of enteral intake, special intravenous amino acid products are available. As BCAA levels approach normal ranges, they must be reintroduced into the diet or hyperalimentation solution as deficiency of BCAAs can lead to skin breakdown and trigger additional catabolic release of BCAAs (188).

Longer-term care of patients with MSUD involves the use of high-calorie diets with limiting amounts of leucine, isoleucine, and valine. Commercial products tailored for these requirements are available. The diets are necessary to maintain BCAA levels at or slightly below the lower range of normal. Thiamine (10–100 mg/day or more) may be trialed to assess the patient for responsiveness, as it helps some patients to stabilize the dehydrogenase complex and allows greater branched-chained amino acid dietary tolerance.

The milder forms of MSUD can normally be managed successfully by dietary intervention. Uniformly excellent clinical results are achieved with this group of patients. Nevertheless, these patients remain vulnerable to acute catabolic episodes; instances of death during adolescence of otherwise normal individuals have been reported (189). Affected women withstand pregnancy well if kept

under good metabolic control, and the small number of children born so far have been normal without evidence of BCAA teratogenicity.

Orthotopic liver transplantation can be carried out for severe MSUD, restoring the functional activity of the missing enzyme. Even as long-term survival is improving with refined surgical techniques, less toxic immunosuppressive regimens, and better postoperative care, the choice to proceed with this procedure must still be balanced with the risks entailed with perioperative complications and chronic rejection (190).

MSUD is inherited as an autosomal recessive condition. The classical form is rare, with an incidence no greater than one in 100,000 live births. Neonatal screening programs have detected a worldwide incidence of one in 185,000. This estimate may be low because it relies on the detection of elevations of BCAAs in the blood or urine samples. At birth, patients with MSUD may have normal levels of BCAAs. With the advent of commercially available genetic testing for all subunits of the BCAA dehydrogenase, enzymatic testing is now rarely used. Prenatal diagnosis and carrier testing are also conducted using sequencing as well because measurement of amino acids or ketoacids in amniotic fluid may not be elevated, even in unborn children with MSUD. Complementary DNA (cDNA) clones for four of the major proteins of the complex  $E_1\alpha$ ,  $E_1\beta$ ,  $E_2$ , and  $E_3$  have been isolated and localized to chromosomes 19q13.2, 6p21, 1p31, and 7q31, respectively. Western and Northern blot analyses have been used to separate the disorder into at least five molecular phenotypes (191,192). Missense, insertion, deletion, splice junction, and apparent regulatory mutations have been identified in the  $E_1\alpha$ ,  $E_1\beta$ , and  $E_2$  genes. No apparent increased incidence of MSUD has been detected in specific ethnic groups, and most of the mutations have been unique to a given family. However, an increased incidence does exist, by founder effect, in the Mennonite population of Pennsylvania; these kindreds have a tyrosine 393 to asparagine missense mutation of the  $E_1\alpha$  gene (193). Because thiamine is bound to the  $E_1\alpha$  subunit, it is surprising that the mutations identified in two thiamine-responsive patients have been in the  $E_2$  gene (194,195).

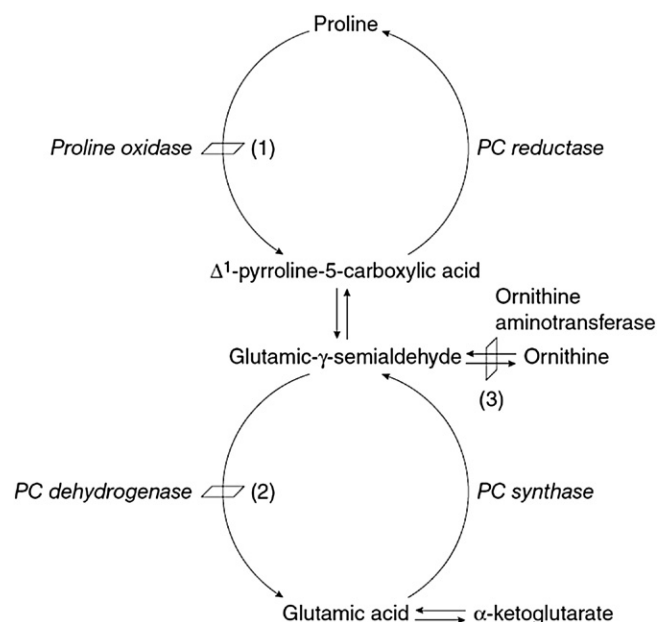

A few individuals with deficiency of the  $E_3$  component have been reported (196). These patients have a clinical presentation similar to that of MSUD and they also have elevations in 2-oxoglutarate and lactate because  $E_3$  is an integral component of the pyruvate and 2-oxoglutarate decarboxylase complexes. The prognosis for this disorder is understandably poor, but at least one patient has responded to therapy with lipoic acid (197).

## 92.6 DISORDERS OF PROLINE AND HYDROXYPROLINE

Proline, a nonessential amino acid, is synthesized from glutamic acid and ornithine through the intermediary

$\Delta^1$ -pyrroline-5-carboxylic acid (PC). The conversion of PC to proline is catalyzed by  $\Delta^1$ -pyrroline-5-carboxylic reductase (P5C). The intermediate in the reaction, PC, is in equilibrium with its noncyclic isomer glutamic- $\gamma$ -semialdehyde via a reversible intramolecular imine/cyclization reaction. The catabolism of proline is almost a reversal of its synthesis but is mediated by separate enzymes. Proline oxidase, also known as proline dehydrogenase, converts proline to PC. PC dehydrogenase further oxidizes the glutamic- $\gamma$ -semialdehyde to glutamic acid. A small amount of glutamic- $\gamma$ -semialdehyde may be converted to ornithine through ornithine aminotransferase. These reactions are summarized in Figure 92-7. Proline oxidase/proline dehydrogenase (PRODH) is a mitochondrial-bound enzyme found only in the kidney, liver, heart, and brain, whereas PC dehydrogenase is more widely distributed and is detectable in cultured skin fibroblasts and blood leukocytes.

Hydroxyproline is formed by posttranslational oxidation of proline residues primarily in collagen, via actions of the prolyl 3-hydroxylase and prolyl 4-hydroxylase complexes. Impaired proline 3-hydroxylation leads to severe, potentially neonatal lethal recessive osteogenesis imperfecta phenotypes (198,199). The catabolism of hydroxyproline is similar to that of proline. Hydroxyproline is first converted to  $\Delta^1$ -pyrroline-3-hydroxy-5-carboxylate by “hydroxy-L-proline oxidase” distinct from proline oxidase.  $\Delta^1$ -Pyrroline-3-hydroxy-5-carboxylate is then oxidized to 4-erythro-hydroxy-L-glutamate by PC dehydrogenase.

**FIGURE 92-7** Biosynthesis and degradation of proline. (1) Proline oxidase deficiency and (2) PC dehydrogenase deficiency are responsible for HPI and HPPII, respectively. (3) Ornithine aminotransferase, the enzyme deficient in gyrate atrophy of the retina, is shown here and in Figure 92-8.

Genetic deficiencies of proline oxidase and PC dehydrogenase exist and are responsible for type I hyperprolinemia (HPI) and type II hyperprolinemia (HPII), respectively. A deficiency of the hydroxy-L-proline oxidase is responsible for hyperhydroxyprolinemia. All are inherited as autosomal recessive conditions. Disorders of proline and hydroxyproline metabolism are reviewed by Phang and colleagues (200).

### 92.6.1 Type I Hyperprolinemia

HPI (OMIM 239500) is caused by deficiency of the *PRODH* enzyme. The original families with HPI were ascertained because of kidney disease, deafness, and neurologic disorders (201). Patients with HPI have increased plasma concentrations of proline (approximately 1000  $\mu$ M) and excrete proline, hydroxyproline, and glycine in the urine. Heterozygotes may have plasma proline values above the normal range. Maternal hyperprolinemia appears to have no effect on the developing fetus (202). Subsequent families with hyperprolinemia were reported as unaffected without clinical problems, and the status of *PRODH* deficiency as a truly pathogenic condition was called into question. The observation of hyperprolinemia in patients with DiGeorge/Velocardiofacial syndrome, which is typically caused by deletions of 22q11, led to the mapping of the *PRODH* gene locus to 22q11.2. Plasma proline levels were found to inversely correlate with intelligence in patients with deletions in 22q11. Schizophrenia, which is a known manifestation in adults with deletion 22q11 syndrome, was also found to correlate with hyperprolinemia (203). *PRODH* sequence variants have been implied as potential risk factors for the development of schizophrenia in conjunction with other modifying genes (204–206). Together with data indicating subtle neurologic dysfunction in *PRODH*-deficient *Drosophila* and *Mus* animal model (207,208), the evidence is emerging that HPI may not be as benign as previously believed.

### 92.6.2 Type II Hyperprolinemia

The clinical significance of HPII (OMIM 239510), caused by a deficiency of the P5C enzyme, is uncertain. The initial reports of the condition were of children with mental retardation and very high plasma proline levels (1500–3000  $\mu$ M), exceeding those of HPI patients. In addition, patients with HPII have substantially high urinary levels of proline, hydroxyproline, glycine, and PC. A study performed on a very large, consanguineous Irish traveler kindred of 312 patients with a proband having severe psychomotor retardation, generalized tonic-clonic seizures, and typical biochemical profile of HPII demonstrated no correlation between HPII and intelligence (209). In the same kindred, there was an association between HPII and seizure disorder. In addition, presumed carrier individuals were identified with

slightly elevated plasma proline without urinary abnormalities. There was no correlation between proline levels in the presumed carriers with only plasma protein elevations in the presence of seizures or psychomotor retardation. Heterozygotes do show partial activity of the dehydrogenase in cultured fibroblasts and blood leukocytes (210). Mutations in the  $\Delta^1$ -pyrroline-5-carboxylate dehydrogenase gene have been shown to be the cause of HPII (211).

### 92.6.3 Hyperhydroxyprolinemia

Hyperhydroxyprolinemia (OMIM 23700) is a rare condition. Similar to HPII, it is considered harmless. Hyperhydroxyprolinemia was originally detected in a child with mental retardation, but subsequent patients have been identified who are mentally and physically normal. Hyperhydroxyprolinemia has been detected in infants through newborn screening programs, and the infants are free of symptoms on long-term follow-up (212). A homozygous woman was found to have normal children (213).

Hyperhydroxyprolinemia is characterized by a markedly elevated concentration of hydroxyproline in the plasma (0.15–0.5 mM; normal less than 0.01 mM). Free hydroxyproline may be much increased in the urine of affected persons, but such concentrations rarely reach a level that interferes with the renal iminoglycine transport system. Thus, the urinary phenotype of hyperhydroxyprolinemia may not include an increased excretion of proline and glycine, as in hyperprolinemia. Heterozygotes do not have elevated levels of hydroxyproline in the plasma and do not excrete increased quantities of hydroxyproline in the urine but may be detectable after a hydroxyproline load. Specific enzyme assays have not been performed to confirm the deficiency. Loading studies using oral hydroxyproline have implied an enzymatic block between hydroxyproline and  $\Delta^1$ -pyrroline-3-hydroxy-5-carboxylic acid, (105,213) suggesting the existence of a separate hydroxyproline oxidase. Subsequent *in vivo* studies confirmed the existence of hydroxy-L-proline oxidase (200).

### 92.6.4 $\Delta^1$ -Pyrroline-5-Carboxylate Synthase Deficiency

$\Delta^1$ -Pyrroline-5-carboxylate synthetase (P5CS) deficiency (OMIM 612652) was reported in two Algerian siblings from a consanguineous union who presented in infancy with failure to thrive, hypotonia, joint laxity, pes planus, hip dislocation, clonic seizures, severe developmental delay, and dysmorphic features including short neck with arachnodactyly. The younger sister had neonatal generalized tonic-clonic seizures. Other clinical findings included skin hyperelasticity, bilateral cataracts, and progressive neurodegeneration beginning after 5 years of age, characterized by loss of independent ambulation, appendicular

dystonia, and peripheral axonal neuropathy. Biochemically, they demonstrated slight hyperammonemia (60–120  $\mu\text{M}$ ); low plasma ornithine, citrulline, arginine, and proline; and normal urinary amino acid levels in the fasted state. Postprandially, levels of ammonia, ornithine, citrulline, and arginine transiently improved or normalized. A pathogenic homozygous p.R84Q mutation in the *P5CS* gene was found, demonstrating a unique inborn error of metabolism in the proline synthetic pathway (214). In a consanguineous Maori family of four affected children with similar skin and joint laxity, joint dislocations, microcephaly, failure to thrive, hypotonia, severe developmental delay, and pyramidal symptoms, a pathogenic homozygous p.H784Y mutation was found in the *P5CS* gene. Biochemically, these patients did not have fasting hyperammonemia and their plasma ornithine, citrulline, and arginine levels were low-normal (215).

The biochemical abnormalities observed in the first family were theorized to be secondary to the pleomorphic effects of cellular proline deficiency arising from deficient *P5CS* activity preventing *de novo* synthesis of proline from glutamate. The dermatologic manifestations of skin hyperelasticity and joint laxity were hypothesized to be as a result of impaired synthesis of collagens, which have a high concentration of proline residues. Similarly, the cataracts were thought to be caused by impaired crystallin synthesis in lens epithelium. Deficiency of proline in the CNS was thought to be the etiology of the severe developmental delay and neurodegeneration. Finally, the biochemical observation of reduced key urea cycle intermediates was explained as a result of deficient *de novo* synthesis of ornithine due to *P5C* deficiency. Without ornithine, the urea cycle cannot progress, resulting in hyperammonemia; the provision of ornithine and arginine with meals in these patients allowed for transient enhancement of urea cycle function (214). The absence of biochemical abnormalities in the second kindred was explained by normal proline biosynthesis from glutamate in their culture fibroblasts (215).

### 92.6.5 Prolidase Deficiency

Special exopeptidases are required for the catabolism of proline-containing dipeptides. X-proline and X-hydroxyproline (where X is any other amino acid) dipeptides are hydrolyzed by prolidase, whereas proline-X and hydroxyproline-X are substrates for prolinase. No patients have yet been identified with prolinase deficiency. Two forms of prolidase are encoded by different genes with different substrate specificities.

Prolidase deficiency (OMIM 170100) is a rare autosomal recessive disorder due to diminished prolidase I activity and has been reviewed by Hechtman (216). Approximately 45 cases have been reported. The disorder demonstrates considerable inter- and intrafamilial variability with respect to clinical manifestations and age of onset.

The earliest age of onset was 3 months and the oldest 22 years, but asymptomatic, prolidase-deficient adults have been occasionally identified (217). The most prominent and consistent finding is recurrent, poorly healing, ulcerative skin lesions. Although ulcerations can occur anywhere, they are usually restricted to the lower extremities. In addition to dermatologic abnormalities, approximately 50% are mentally retarded to varying degrees. About 30% have splenomegaly and 45% have recurrent upper respiratory tract infections. Mild dysmorphic features are frequently noted in adults, including frontal bossing, a low frontal hairline, saddle nose, and mild prognathism. Persons with prolidase deficiency excrete large quantities of iminodipeptides in the urine. The diagnosis may be confirmed by enzymatic assay of erythrocytes or cultured skin fibroblasts. Heterozygotes have half-normal activity.

The pathogenesis of the cutaneous and systemic manifestations of prolidase deficiency is poorly understood. Prolidase I has been cloned and mapped to chromosome 19q12-q13.11. Other than supportive care, no consistently effective therapy has been found (218).

## 92.7 DISORDERS OF THE UREA CYCLE AND ORNITHINE

The urea cycle is a six-step pathway that results in the conversion of two molecules of ammonia and one molecule of bicarbonate to urea. It is the only major metabolic pathway for the removal of waste nitrogen formed from protein turnover or ingestion and occurs primarily, if not exclusively, in the liver. High levels of ammonia in the blood and tissue result in toxicity to the CNS. The primary effect of elevated ammonia appears to be the uptake of fluid into astrocytes, causing cerebral edema. Ammonia metabolism and the urea cycle disorders are reviewed by Brusilow and Horwich (219).

Complete deficiency of any of the enzymes 1–5 (Figure 92-8) leads to severe hyperammonemia during the neonatal period, with symptoms of lethargy, poor feeding, coma, and often death. Ammonia levels often exceed 1000  $\mu\text{M}$  (normal less than 50). Partial enzyme deficiencies may delay onset of clinical symptoms until later in life and may be associated with lower ammonia levels. The presentation could be indolent or an acute catastrophic collapse in conjunction with some infectious event or parturition. With episodes of hyperammonemia, nausea and vomiting may be the initial or the only symptoms. Many patients who have suffered severe hyperammonemic crises experience sequelae of psychomotor delay, learning disabilities, attention deficit disorder, or other neurologic abnormalities.

The enzymatic basis of hyperammonemia can usually be inferred from determination of the plasma amino acid levels, acid–base balance, urinary organic acids, and urinary orotic acid. Specific confirmation by enzymatic assays is desirable whenever possible. Therapy is both generic and disorder-specific and is detailed in the next section.

Hyperammonemia with generalized aminoacidemia and relatively normal acid-base balance is the typical biochemical presentation. When the enzyme deficit is severe, plasma citrulline levels are practically undetectable. It is distinguished in the acute presentation from ornithine transcarbamylase (OTC) deficiency by normal or reduced levels of orotic acid in the urine. Treatment is the same as that for urea cycle disorders (see later).

More than 220 mutations have been described in the *CPS1* gene, of which 90% are unique, “private” mutations; as noted above, sequencing of *CPS1* and *NAGS* is the only way to distinguish the two disorders apart since clinical presentations and biochemical profiles are very similar (228).

One or more polymorphisms in the *CPS1* gene that reduce activity modestly may diminish the arginine biosynthetic reserve and be associated with a poorer outcome in patients with conditions dependent on nitric oxide synthesis for their mitigation (229).

### 92.7.3 OTC Deficiency

OTC is a mitochondrial matrix enzyme and catalyzes the condensation of carbamoylphosphate and ornithine to form citrulline. The gene encoding OTC is at Xp21.1. Patients with OTC deficiency (OMIM 300461), like other inborn errors of metabolism, represent a range of disease severity correlating with degree of residual enzymatic function.

Children with severe OTC deficiency are usually hemizygous males who manifest symptoms in infancy, often in the first 48–72 h of life. The catabolic processes that occur in the neonatal period from stress and dehydration, compounded with the inability to detoxify ammonia liberated by protein catabolism, led to increasing accumulation of blood ammonia. Infants with progressive hyperammonemia are initially irritable and feed poorly. These symptoms may be accompanied with vomiting, which further exacerbates catabolism. Tachypnea and metabolic alkalosis occur as a result of initial stimulation of the brainstem respiratory centers. Eventually, profound hyperammonemia (often exceeding 1000  $\mu\text{M}$ ) leads to encephalopathy and seizures. Many infants who reach this degree of hyperammonemia succumb or suffer profound brain injury if resuscitated. Patients with partial deficiency of OTC may present during the neonatal period or later in infancy, with similar symptoms of altered level of consciousness and vomiting; they are often incorrectly diagnosed with viral encephalitis or aseptic meningitis if ammonia levels are not examined during episodes of lethargy. Inciting events for hyperammonemia for partial deficiencies are usually intercurrent illnesses that precipitate protein catabolism; they may also develop symptoms when solid foods are introduced into the diet, increasing their protein intake beyond what their limited OTC enzymatic activity can handle. Heterozygous girls can also develop symptoms of hyperammonemia. If a large proportion of their hepatocytes inactivate the X-chromosome bearing the wild-type OTC gene, their symptoms can be as severe as the neonatal-onset hemizygous males (230). At least one patient with arginase deficiency became hyperammonemic at the time of her menstrual period (231), and a similar phenomenon in some female OTC carriers would not be unexpected. Additionally, asymptomatic heterozygotes

are known to develop hyperammonemic crises following childbirth, a result of protein catabolism incited by fasting and rapid involution of the myometrium (232). Finally, OTC deficiency can manifest in adulthood not only with hyperammonemic crises but also with psychiatric disturbance akin to delirium or psychosis. Most surviving patients with OTC deficiency are heterozygous women or hemizygous men with milder missense mutations, allowing residual enzymatic function. Older survivors, even “asymptomatic” heterozygotes, often report spontaneous aversion to dietary protein.

Biochemically, symptomatic OTC patients develop hyperammonemia, generalized aminoaciduria, and aminoacidemia, with particular elevations in plasma glutamine, alanine, lysine, and glutamate. The citrulline concentration is reduced and may be undetectable. In contrast to CPS-I and NAGS deficiencies, excretion of orotic acid in the urine of patients with OTC deficiency is markedly elevated. This occurs because the accumulated carbamoylphosphate is shunted to pyrimidine metabolism through CPS-II (see Figure 92-8). CPS-II is a different enzyme from CPS-I; it is located in the cytoplasm and requires glutamate as a cofactor. Patients with partial OTC deficiency and intermittent symptoms may have normal orotic acid excretion and plasma citrulline concentration when they are clinically well.

OTC is found primarily in the liver and is not detectable in the cultured fibroblasts or leukocytes. In severely affected men, the enzyme is virtually absent, with less than 1% of normal activity. In symptomatic women, enzymatic activity has been shown to vary from 10 to 40% of normal.

The gene for OTC has been shown to be X-linked by pedigree data, by the demonstration of two populations of hepatocytes in female carriers, and by genetic linkage and in situ hybridization using cloned cDNA. Most patients with suspected OTC deficiency are now confirmed utilizing sequencing of the OTC gene. Historically, carrier status in females was confirmed utilizing the “allopurinol challenge test,” proposed by Brusilow and colleagues (233). The drug inhibits orotidine metabolism and allows the detection of orotic acid and orotidine in the urine of female carriers under standard conditions. OTC carriers will have higher levels than detected in noncarriers. This same test was also used to detect males with partial OTC deficiency and intermittent symptoms and biochemical abnormalities.

Direct mutation permits prenatal diagnosis in most pregnancies of women who are known carriers of OTC. Numerous point mutations have been described in patients with severe disease, as well as those who are more mildly affected. In one study, 7% of deficient males but 80% of OTC-deficient women had new mutations (234). However, even if the mother does not have the mutation in the somatic cells, recurrence can occur because of gonadal mosaicism (235).

Outcome in the acute form of this disease is uniformly poor. Those who survive the acute hyperammonemia as newborns are usually left with severe neurologic impairment and are subject to recurrent episodes of hyperammonemia, one of which is usually fatal (236). Milder manifestations are more successfully managed by the methods outlined later. Because of the inevitability of severe brain damage, patients diagnosed presymptomatically and those rescued successfully from coma eventually become candidates for preemptive orthotopic liver transplantation. Efforts to develop gene therapy, often in conjunction with hepatocyte transfer, are ongoing.

#### 92.7.4 Citrullinemia Caused by Deficiency of Argininosuccinic Acid Synthetase

The condensation of citrulline, previously transported out of the mitochondrion, and aspartate to form argininosuccinic acid (ASA) is catalyzed by ASA synthetase (see Figure 92-8). Deficiency of this enzyme (OMIM 215700) leads to citrullinemia, citrullinuria, hyperammonemia, and orotic aciduria. The disorder, once called citrullinemia, is now known as citrullinemia type I or ASA synthetase deficiency owing to the recent characterization of “citrullinemia type II,” a disorder of mitochondrial aspartate transport (covered below). The diagnosis of citrullinemia type I is not difficult because elevated amounts of citrulline are found in both plasma and urine.

The clinical picture of patients with citrullinemia type I varies in severity according to residual enzymatic activity; some patients have so benign a course that no disorder is suspected. Age of presentation varies from the neonatal period to adulthood and presenting symptoms mirror those of OTC deficiency (covered above).

ASA synthetase deficiency is inherited in an autosomal recessive manner. Molecular genetic testing is used to confirm the diagnosis and is also used for prenatal diagnosis. Prenatal diagnosis can also be accomplished by measurement of amniotic fluid citrulline, which is usually elevated in the unborn affected. More than 80 mutations have been identified (237). With the exception of the IVS6-2A>G mutation in the Japanese and the p.G390R panethnic mutation, none are common or recurrent (238). Newborn screening by tandem mass spectrometry has successfully identified patients affected by this disorder, including the cases on the mildest end of the spectrum.

#### 92.7.5 Argininosuccinic Aciduria

ASA is cleaved into two smaller molecules, arginine and fumarate, in an equilibrium reaction catalyzed by ASA lyase. The enzyme is active in the liver, brain, and kidney. In the latter organ, at least, working in concert with

ASA synthetase, it is responsible for synthesizing most of the arginine used for biosynthetic purposes. Deficiency of ASA lyase leads to marked elevations in ASA in the plasma, urine, and CSF, and in a variety of tissues. The enzyme is also measurable in the red blood cells and fibroblasts.

Symptoms associated with ASA lyase deficiency (OMIM 207900), like the other urea cycle disorders presented, range in severity. Profoundly deficient cases present in the neonatal period with lethargy, vomiting, and poor feeding, and cannot be clinically differentiated from other neonatal-onset urea cycle disorders. Without treatment, the hyperammonemia leads to cerebral edema, coma, seizures, and eventually death. The disorder can also present later in childhood with hyperammonemia following an intercurrent illness or with nonspecific developmental delay, behavioral problems, and learning disabilities. All patients who are arginine-deficient appear to have at least some degree of trichorrhexis nodosa, a condition that causes friable, nodular hair. Features of ASA lyase deficiency that distinguish it from other disorders previously presented include a propensity toward hepatic fibrosis and hypertension. In addition, a higher proportion of patients with this condition have neurobehavioral dysfunction, including attention-deficit hyperactivity disorder, seizure disorder, learning disability, and developmental delay compared to other urea cycle disorders (239). While not definitively proven, nitric oxide deficiency and accumulation of toxic, oxidative adducts of argininosuccinate like guanidinosuccinate have been advanced as explanations for the additional symptoms seen in ASA lyase deficiency (239). However, normal psychomotor development is possible with early supplementation of arginine and prevention of hyperammonemia.

Biochemically, patients with this condition have less profound elevation in plasma citrulline (100–300  $\mu$ M) compared to those with citrullinemia type I. Alanine and glutamine elevation may be present, reflective of hyperammonemia. ASA and its anhydrides will also be present in the amino acid chromatogram.

ASA lyase deficiency is inherited in an autosomal recessive manner. Molecular sequencing for the *ASL* gene is clinically available and allows diagnostic, carrier, and prenatal testing. Sequencing of the ASA lyase cDNA has demonstrated remarkable similarity to the lens structural protein  $\delta$ -crystallin. Duck crystallin has ASA lyase activity. The significance of these provocative findings for both biochemistry and evolution still remain to be determined. Elevated citrulline in dried blood spots is the basis for newborn screening for this condition.

#### 92.7.6 Hyperargininemia

Like the previous two disorders, a defect in arginase, the final enzyme in the urea cycle that catalyzes the hydrolysis

of arginine to urea and ornithine, is named after the substrate that accumulates as a result of its deficiency. Arginase is most active in the liver but is expressed at lower levels in a variety of other tissues, including red blood cells. Red blood cells may be used to measure the enzyme for diagnosis (240). A second isozyme of arginase, encoded by a separate gene, is localized to the mitochondrion, is more widely distributed than its more abundant namesake and appears to normally function in the synthetic pathways of ornithine, polyamines, and nitric oxide (241,242).

Clinical symptoms of liver arginase deficiency (OMIM 207800) are more subtle and occur at a later age than those of the other urea cycle defects. Recognized episodes of hyperammonemia are the presenting symptoms in only a minority of patients. At the age of 1–3 years, linear growth slows and spasticity begins to develop several years later. Soon, previously normal cognitive development slows or stops and the child begins to lose developmental milestones. If untreated, arginase deficiency usually progresses to severe spasticity, loss of ambulation, complete loss of bowel and bladder control, and severe intellectual disability. Argininemia is the only urea cycle defect in which cortical and pyramidal tract signs predominate. However, because of early recognition and initiation of treatment, more than 80% of reported patients are still alive and some are older than 30 years. It seems likely that the mild clinical course in these patients is due to the presence of residual activity as a result of the existence of the second arginase isozyme, whose activity appears augmented as a consequence of hyperargininemia. Although most patients are severely retarded, therapy is beneficial, preventing symptoms and preserving cognition if begun early and preemptively.

An increased concentration of arginine is found in the plasma and CSF of all patients, but urinary amino acid excretion may be normal in some patients most of the time and in all patients some of the time. The pattern of urinary amino acid excretion may be confused with cystinuria. Patients with argininemia have elevated levels of body fluid guanidinoacetate, an intermediate of creatine biosynthesis generated from donation of the guanidinium group of arginine to glycine. Guanidinoacetate and other guanidinium compounds have been shown to be neurotoxic (243) and may be responsible for the pyramidal signs and neurodegeneration seen not only in argininemia but also in patients with guanidinoacetate methyltransferase deficiency.

Arginase deficiency is inherited in an autosomal recessive manner; parents exhibit half-normal arginase activity. Molecular genetic testing allows clinical and prenatal diagnosis. A number of different mutations have been found in the affected individuals but none in sufficient frequency to be readily useful clinically (242). Arginine levels in blood are likely to be elevated in most newborns with this disorder, and screening by tandem mass spectrometry can detect these individuals presymptomatically.

### 92.7.7 Citrullinemia Caused by Citrin Deficiency

Significant strides have been made in characterizing the natural history of this disorder, caused by a deficiency of citrin, a mitochondrial aspartate/glutamate antiporter encoded by the *SLC25A13* gene (244). Citrin deficiency appears to have a bimodal age of onset, with a neonatal presentation (neonatal intrahepatic cholestasis caused by citrin deficiency (NICCD)) and an adult-onset presentation (termed “citrullinemia type II” (CTLN2)). Infants with NICCD are sometimes identified via newborn screening and display markers of neonatal cholestasis, with elevated phenylalanine or methionine. Newborns may also screen positive for galactosemia if galactose is used as the marker for the disorder and not galactose-1-phosphate uridylyltransferase activity (245). Clinically, infants with NICCD demonstrate some combination of failure to thrive, poor feeding, prolonged jaundice, and cataracts. Laboratory investigations indicate signs of cholestasis and liver synthetic dysfunction: liver transaminases, alkaline phosphatase, and  $\gamma$ -glutamyltranspeptidase levels are high, as are coagulation times, conjugated bilirubin and bile acid levels. Low-level hyperammonemia may be present, usually not exceeding  $70\text{ }\mu\text{M}$ . Plasma citrulline levels are elevated (median  $300\text{ }\mu\text{M}$ ) but not as high as classical ASA synthase-deficient patients. Plasma amino acids are also indicative of liver dysfunction and cholestasis, with tyrosine, methionine, and threonine elevations approximately two to four times the upper limit of normal (246). Liver biopsies performed on infants with NICCD have demonstrated micro- and macrovesicular steatosis in addition to fibrosis. With the exception of several patients whose liver synthetic function deteriorated to require orthotopic liver transplantation (247), most infants with NICCD experience resolution of the cholestasis and liver dysfunction, entering a “compensated” oligosymptomatic phase. After their first birthday, they develop peculiar dietary habits, eschewing high-carbohydrate foods and preferring high-protein and high-fat foods, especially beans and peanuts (248). During this phase, patients may complain of nonspecific constitutional symptoms such as nausea, fatigue, reduced appetite, headaches, and abdominal pain.

Symptoms of CTLN2 generally begin in early adulthood, although age of first presentation has ranged from 11 to 79 years, and resemble the symptoms of later-onset urea cycle disorders (249). Most suffer from sudden-onset altered mental status, disorientation, lethargy, and restlessness, and progress to coma. Others have been reported to have intermittent “psychosis,” delusions, delirium, and seizures. Death may occur from irreversible cerebral edema induced by hyperammonemia. CTLN2 patients continue to demonstrate a preference for foods rich in protein and fat, as intake of alcohol or a carbohydrate-rich meal will precipitate symptoms. Biochemically, plasma ammonia, citrulline, and arginine

levels are elevated, while hyperbilirubinemia, hypertyrosinemia, and hypermethioninemia seen in NICCD are absent. For unknown reasons, the amount of hepatic ASA synthase protein declines even without ASA synthase mutations or reduced messenger RNA levels. Pancreatitis, hyperlipidemia, and hepatocellular carcinoma have been reported in a minority of CTLN2 patients (246). Although most NICCD infants go on either to develop full CTLN2 or to the oligosymptomatic phase, a small percentage stay healthy as adults. This is evidenced by the drop in prevalence from 1:17,000 live births in Japan for NICCD to 1:100,000–230,000 for CTLN2 (250). Furthermore, the ratio of males to females affected with NICCD is approximately 1:1, consistent with its autosomal inheritance, but the ratio of males to females with CTLN2 increases to 2.4:1, indicating the existence of currently unknown factor(s) that partially protects women from the latter phenotype (250).

While molecular sequencing of SLC25A13 is clinically available, perhaps serum pancreatic secretory trypsin inhibitor (PTSI) can be utilized as a screening test where NICCD or CTLN2 is suspected, as nearly all affected individuals where PTSI was checked demonstrated elevated levels of this marker. Most patients with SLC25A13-associated disorders are of East Asian origin, especially Japanese, Southern Chinese, Taiwanese, and Korean descent, but the disease is not restricted solely to these ethnicities (154).

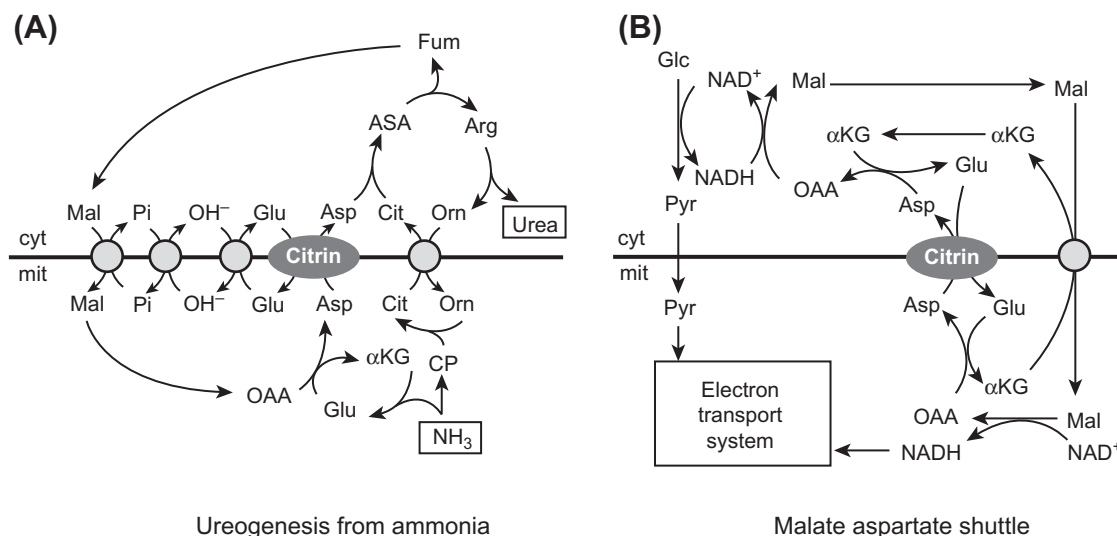

The pathogenesis of the disorder appears to be as a result of aspartate's participation in multiple biochemical pathways. Without proper citrin function, endogenous aspartate becomes sequestered within the mitochondria (Figure 92-9). Because the ASA synthase reaction takes place within the cytosol, ureagenesis is impaired as cytosolic aspartate deficiency prevents production of ASA and results in accumulation of citrulline

and ammonia. In addition, because of the key role played by aspartate via the malate:aspartate shuttle in transporting cytosolic NADH across the mitochondrial inner membrane, citrin deficiency results in accumulation of NADH in the cytosol. The abnormal NADH:NAD<sup>+</sup> ratio subsequently impairs gluconeogenesis, glycolysis, and alcohol metabolism. These mechanisms offer a partial etiology for citrin-deficient patients' preference for protein, augmenting exogenous aspartate intake in order to replenish both the cytosolic arm of the urea cycle and malate:aspartate shuttle. They also explain citrin-deficient patients' avoidance of carbohydrate and alcohol to avoid exacerbation of existing cytosolic NADH:NAD<sup>+</sup> imbalance (251).

Infants with NICCD should be treated with a combination of medium chain triglyceride-containing formula with higher fat and protein content, supplementation with fat-soluble vitamins, and elimination of galactose from the diet. CTLN2 patients can be treated with a similar high-fat, high-protein diet, arginine supplementation, and avoidance of alcohol and high-carbohydrate foods. This combination aims to reduce the cytosolic NADH:NAD<sup>+</sup> ratio and can treat hyperammonemia, hypertriglyceridemia, and steatosis. Intravenous resuscitation for CTLN2 patients runs counter to emergency treatment for most other inborn errors, as infusions of glucose and glycerol have been reported to precipitate sudden hyperammonemia and coma (250). Ultimately, orthotopic liver transplantation has been performed in CTLN2 patients, resulting in abolition of hyperammonemic crises and resolution of the dietary protein/fat preference.

### 92.7.8 Treatment of Urea Cycle Disorders

The two linchpins of therapy for urea cycle disorders are the diminution of the amount of ammonia that must

**FIGURE 92-9** The function of the citrin protein in relation to the (A) urea cycle and (B) the malate aspartate shuttle. In each instance, it is the proper efflux of aspartate from the mitochondria to the cytosol that allows each cycle to proceed. (With permission from Saheki et al. 2010.)

be detoxified and the removal of the ammonia that is formed. Treatment can be divided into that for acute life-threatening hyperammonemia and that used chronically between episodes to keep ammonia levels at near-normal values. The details of these approaches are well described (219). Ammonia is derived from the amino acids of protein, either ingested or endogenously catabolized as part of normal turnover or breakdown and heightened by intercurrent events. Over the short term, increased catabolism presents a far greater threat and must be more feared than small variations in exogenous protein intake. Any more than 12–15 h of anorexia and caloric deprivation is likely to trigger protein catabolism and hyperammonemia.

Severe hyperammonemia ( $>400$ – $500\mu\text{M}$ ) will require hemodialysis to remove ammonia in a timely fashion to reduce the likelihood of permanent brain injury. However, there may already be irreversible brain damage by the time treatment is initiated, especially in cases of neonatal hyperammonemic coma. In the face of significant cerebral edema and an increased head circumference, the parents should be counseled about the neurologic outcome before any specific therapy for hyperammonemia is begun.

During hyperammonemic crisis, maintenance of fluid intake with high carbohydrate-containing liquids is essential to reduce glucagon-mediated protein catabolism and subsequent ammonia release. If unsuccessful, earlier rather than later intravenous intervention is recommended to prevent severe hyperammonemia. Provision of sufficient calories in the form of high dextrose infusion rate (greater than  $6\text{ mg/kg/min}$  glucose infusion rate) and intralipid infusion will remove the hypoglycemic stimulus to protein catabolism. In the first 24–48 h of hyperammonemic crisis, exogenous protein can be excluded to reduce potential sources of nitrogen, but afterward protein should be reintroduced ( $0.5$ – $1\text{ g/kg/day}$ ) to prevent additional catabolism and ammonia release induced by prolonged removal of protein.

A major breakthrough in the therapy for these disorders occurred when Brusilow and colleagues (219) devised a number of means to divert ammonia from urea production and to reduce plasma ammonia. These involve the recognition that arginine may become an essential amino acid and that indirect removal of amino acids in the process of organic acid detoxification will divert nitrogen away from the urea cycle. The amino acid product of the first two steps of the urea cycle catalyzed by CPS-I and OTC is citrulline; the next two steps catalyzed by ASA synthetase and ASA lyase convert citrulline to arginine. Hydrolysis of arginine produces ornithine, needed to react with carbamoylphosphate, which carries the first of the two ammonia molecules destined to be excreted as urea. All patients with deficiencies of the first four enzymes of the urea cycle may be deficient in arginine, and

arginine supplementation is an appropriate part of the therapy. In fact, during periods of hyperammonemic crisis, intravenous arginine ( $250\text{ mg/kg/day}$  as a constant drip) in conjunction with high caloric infusion can significantly bring down ammonia levels as intravenous solutions of nitrogen-scavenging medications are being procured and prepared. In patients with CPS-I or OTC deficiency, the substitution of citrulline for arginine is desirable; citrulline is converted efficiently to arginine and in the process removes another nitrogen molecule from the ammonia pool. In the case of ASA synthetase and ASA lyase deficiencies, higher amounts of arginine reduce blood and body ammonia levels and promote their conversion to the more readily excreted compounds citrulline and argininosuccinate. The use of arginine in these two conditions, but ASA lyase deficiency in particular, effectively eliminates episodes of hyperammonemia.

The organic anions benzoate and phenylacetate (or phenylbutyrate) are known as “ammonia-scavenging” medications because they are excreted as benzoylglycine (hippurate) and phenylacetylglutamine, respectively. Resynthesis of glycine requires one molecule of ammonia and two molecules of glutamine. Administration of either compound or both in stoichiometric amounts diverts ammonia from the urea cycle, and in patients with urea cycle defects, it reduces the accumulation of ammonia and other metabolites proximal to the enzymatic deficiency. An intravenous preparation of sodium benzoate and phenylbutyrate (Ammonul; Hyperion Therapeutics) is used for patients with deficiencies of NAGS, CPS, OTC, ASA synthetase, and ASA lyase in severe hyperammonemic crisis.

Maintenance therapy for a patient with a urea cycle disorder follows the same principles as those for acute treatment. To reduce ammonia-generating substrate, dietary intake of protein should be limited to  $1$ – $2\text{ g/kg/day}$  for infants and  $0.5$ – $1.0\text{ g/kg/day}$  for older children. The quality of the dietary protein may be enhanced by the use of an essential amino acid preparation, if required. Surprising flexibility in protein intake is permitted, provided plasma levels of amino acids approximate the normal range and hypoaminoacidemia is not permitted to function as a stimulus to endogenous protein catabolism. Second, urea cycle intermediates distal to the enzymatic block should be given to replenish the urea cycle and allow additional ammonia detoxification. For CPS and OTC deficiencies, either oral arginine hydrochloride or citrulline  $150\text{ mg/kg/day}$  can be administered; for ASA synthetase and ASA lyase deficiencies, arginine hydrochloride concentration up to  $700\text{ mg/kg/day}$  should be given to normalize plasma arginine levels. Finally, oral sodium benzoate ( $250\text{ mg/kg/day}$ ) or sodium phenylbutyrate ( $250\text{ mg/kg/day}$ ) is used as an ammonia-scavenging medication. Their use has greatly diminished the frequency and intensity of intercurrent hyperammonemic episodes and has been

associated with a markedly improved prognosis for patients with these disorders. Valproic acid should not be used as an anticonvulsant in patients with urea cycle defects because this medication provokes severe hyperammonemia in almost all cases.

Patients with severe urea cycle defects, such as males with complete OTC deficiency, who have not suffered significant neurologic damage, are candidates for liver transplantation. Liver transplantation is an effective “cure” for the metabolic disorder, especially as surgical techniques, postoperative care, and antirejection regimens have undergone considerable refinement to reduce the attendant morbidity and mortality from the procedure (252,253).

Mouse models, occurring either naturally or as a result of gene “knockout” experiments, are available for all six steps of the urea cycle and should prove useful in the development of gene and other therapies for the urea cycle defects.

### 92.7.9 Lysinuric Protein Intolerance

Lysinuric protein intolerance (LPI, OMIM 222700) is a deficiency of the  $\gamma^+$ LAT-1 light chain subunit of the cationic amino acid transporter  $\gamma^+$ L, impairing transport of positively charged amino acids such as lysine. This disorder is reviewed in depth by Sebastio (254). LPI has severe, multisystemic effects owing to deficient egress of lysine, ornithine, and arginine from the epithelial basolateral membranes. Infants present usually after weaning of breastfeeding or formula, with failure to thrive, vomiting, diarrhea, and poor feeding. Lethargy, altered level of consciousness, and vomiting may occur after ingestion of high-protein foods. In fact, LPI patients will self-select their diets to avoid foods rich in protein. Hepatosplenomegaly also occurs and may lead to misplaced suspicion of a lysosomal storage disorder, although typically accompanied by hematologic derangements similar to hemophagocytic lymphohistiocytosis (255,256). Other chronic, life-threatening complications of LPI include progressive alveolar proteinosis leading to respiratory failure and renal manifestations such as proteinuria, microscopic hematuria, Fanconi syndrome, hypertension, and eventual, dialysis-dependent, end-stage renal disease (254). Many patients experience developmental delay, and older patients may manifest psychiatric symptoms.

Biochemically, LPI patients have low plasma lysine, ornithine, and arginine levels. There is elevated excretion of these dibasic amino acids in the urine, but cystine excretion is normal. Hyperammonemia results most likely from insufficient reabsorption of ornithine and arginine from the renal tubular epithelium, leading to hepatocellular depletion of these amino acids and inadequate ureagenesis. Orotic aciduria is also present (257). Systemic depletion of dibasic amino acids results in protein malnutrition and failure to thrive. Trapping

of arginine in leukocytes and in the epithelium of the kidneys and lungs is theorized to result in nitric oxide overproduction, leading to apoptosis and release of inflammatory mediators. It is derangement of tightly regulated nitric oxide production that is thought to lead to the progressive renal and pulmonary failure, along with the bizarre hematologic manifestations of the disease.

Treatment for LPI is complex and requires multidisciplinary care. Reduction of ammonia levels with protein restriction, citrulline supplementation, and sodium benzoate is but one facet. Oral L-lysine supplementation should be provided (258). Treatment of pulmonary alveolar proteinosis, renal disease, and hemophagocytic lymphohistiocytosis should be handled by pulmonologists, nephrologists, and hematologists. For patients with short stature and growth hormone deficiency, administration of human growth hormone may be considered.

More than 50 mutations in the *SLC7A7* gene, which encodes  $\gamma^+$ LAT-1, have been identified in LPI. LPI, although a panethnic disorder, is more common in Finland, where the g.IVS6-2a>t splice site mutation is present in most cases due to founder effect (259,260).

### 92.7.10 Hyperinsulinemia-Hyperammonemia Syndrome

This condition (OMIM 606762) is caused by dominant mutations in the glutamate decarboxylase gene that result in increased enzymatic activity. The enzyme, which catalyzes the conversion of glutamate to  $\alpha$ -ketoglutarate, is allosterically activated by leucine and inhibited by GTP. Release of  $\alpha$ -ketoglutarate indirectly stimulates insulin release from pancreatic  $\beta$ -cells by closing the SUR/KIR6.2 potassium efflux channel. Activating mutations increase sensitivity of the enzyme to leucine or reduce the inhibitory effect of GTP, leading to constitutive conversion of glutamate to  $\alpha$ -ketoglutarate and subsequent hyperinsulinism (261,262). Affected patients present often in the neonatal period with recurrent episodes of hyperinsulinemic hypoglycemia, sometimes misinterpreted as seizures, delaying the diagnosis and increasing the probability of permanent brain injury. The hypoglycemia can be provoked by both fasting and ingestion of a protein-rich meal. Hyperammonemia is usually two to four times upper limit of normal, increments minimally following ingestion of protein, and is usually not accompanied by elevations in plasma glutamine (263). *In vitro* studies in animal models indicate that the source of ammonia is not from urea cycle impairment in the liver, as originally thought, but rather from the increased production from the kidney. The disorder is readily treatable with diazoxide, which suppresses insulin secretion; restriction of protein may help in some cases to prevent postprandial hypoglycemia (264).

### 92.7.11 The Hyperornithinemias

Two inborn errors of metabolism produce elevated levels of plasma ornithine: (1) gyrate atrophy of the retina with hyperornithinemia and (2) hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome. These disorders are reviewed by Valle and Simell (265).

### 92.7.12 Gyrate Atrophy with Hyperornithinemia

Gyrate atrophy of the retina (OMIM 258870) is usually associated with a 10- to 20-fold elevation in plasma ornithine and no hyperammonemia. The disorder primarily affects vision, typically with no associated problems in intellectual development. Visual loss begins to occur by the end of the first decade (myopia and decreased night vision). By the second decade, there is reduced peripheral vision. Cataracts develop by the second or third decade, and most patients are blind by the fifth decade of life. The progression can be more rapid and may accelerate during puberty. There is quite a bit of variability even among patients homozygous for the recurrent L402P Finnish mutation (266). The retinal atrophy begins in the periphery, with loss of the pigment epithelium. The fundal picture is characterized by sharply defined margins of choroidal atrophy, slowly progressing toward the posterior pole of the eye. Some patients have mild proximal muscle weakness and type 2 muscle fiber atrophy with tubular aggregates in the fibers. Ten percent of patients have a clinically significant peripheral neuropathy, but 50% have abnormal electrophysiologic testing (267). Abnormalities in the brain on MRI and abnormal EEGs are common, indicating potential dysfunction of the CNS even in cognitively normal patients (268). A cohort of mentally impaired gyrate atrophy patients were discovered to have abnormally low plasma creatine and guanidinoacetate levels, with severely reduced creatine peaks on brain magnetic resonance spectroscopy (269). Systemic creatine deficiency in gyrate atrophy is a secondary phenomenon resulting from the inhibitory effect of elevated ornithine levels on the first step of creatine synthesis, the conversion of arginine and glycine to ornithine and guanidinoacetate.

Gyrate atrophy is an autosomal recessive disorder caused by a deficiency of ornithine  $\delta$ -aminotransferase (OAT; see Figure 92-8), which transaminates ornithine to glutamate-5-semialdehyde. While the disorder occurs in all ethnicities, it is most common in the Finnish population, with an incidence of 1 in 50,000.

Certain patients with gyrate atrophy have experienced reduction in plasma ornithine levels following administration of pyridoxine or pyridoxal phosphate, but its effects on retinal atrophy and vision loss are not certain. Similarly, creatine supplementation is able to correct the systemic phosphocreatine deficiency but does not

appear to slow the progression of vision loss (270). On the other hand, restriction of dietary ornithine and arginine has successfully delayed chorioretinal degeneration (271,272). An OAT knockout mouse develops retinal degeneration and should help elucidate the pathogenesis and allow testing of potential therapies (273).

### 92.7.13 HHH Syndrome

The HHH syndrome (OMIM 238970) occurs as a result of deficiency of the mitochondrial ornithine translocase encoded by the *SLC25A15* gene (274). The transporter brings cytosolic ornithine into the inner mitochondrial matrix, where the ornithine is transcarbamylated to citrulline. Without proper function of ornithine translocase, the urea cycle has insufficient ornithine substrate to proceed with ureagenesis and ammonia detoxification. Consequently, patients with HHH syndrome develop hyperammonemia (at most three times upper limit of normal) and elevated plasma ornithine (200–700  $\mu$ M, normal < 135  $\mu$ M). The “milder” hyperammonemia seen in HHH syndrome compared to other urea cycle disorders is probably due to the existence of a second ornithine transporter that is able to partially compensate for the lack of the first. The gene for the second transporter (*SLC25A2*) is encoded by a homologous, intronless gene that apparently arose from *SLC25A15* by retrotransposition (275,276). The homocitrullinuria is thought to arise from transcarbamylation of lysine, which is similar in chemical structure to ornithine, with the exception of an additional methylene group in its side chain. Orotic aciduria is also present due to shunting of unused carbamoyl phosphate into the pyrimidine biosynthetic pathway.

The clinical symptoms of HHH syndrome are variable, with neonatal hyperammonemic coma, infantile failure to thrive, adult-onset fulminant liver failure, and stroke-like episodes, all described as initial presentations (277,278). Much like ASA lyase deficiency and argininemia, neurocognitive impairment occurs with high frequency even in those without hyperammonemia under good metabolic control, although normal cognition is possible (279). Developmental delay, seizure disorder, and pyramidal signs occur in a large proportion of patients (278,280). In addition, hepatic synthetic function is also frequently impaired, manifesting as elevated transaminases and prolonged coagulation times. Despite the hyperornithinemia, HHH syndrome patients do not develop the retinal changes associated with ornithine aminotransferase deficiency.

Molecular genetic sequencing is available to confirm the diagnosis of HHH syndrome; over 30 mutations have been ascertained. Currently, the only recurrent ancestral mutation is the p. $\Delta$ F188 in-frame deletion that is found in the French Canadian population. Although the mutation results in minimal expression of functional protein secondary to proteolysis via the endoplasmic reticulum-associated degradation system, the clinical

manifestations of even homozygous p.ΔF188 patients are very heterogenous (280).

Treatment is symptomatic and involves limiting protein intake, supplementation with citrulline, and diverting ammonia from the urea cycle using sodium benzoate and sodium phenylbutyrate.

## 92.8 DISORDERS OF SERINE METABOLISM

Serine is a nonessential polar amino acid with multiple important functions in the body. Catalyzed by serine hydroxymethyltransferase, one-carbon units in the form of  $N^{5,10}$ -methylenetetrahydrofolate are generated from serine for use in purine and pyrimidine biosynthesis and methylation reactions. Sphingolipids and phospholipids, important cell membrane components, are derived from serine. The enantiomer, L-serine, found in proteins and lipids, is converted to the facultative neurotransmitter D-serine via the action of the serine racemase enzyme. L-serine is also an important neurotrophic factor in the CNS, an observation that led to the description of three inborn errors of serine synthesis.

### 92.8.1 Disorders of Serine Synthesis

In addition to dietary protein and catabolism from phospholipids, serine is synthesized endogenously from two sources: the first, from glycine in the reverse reaction catalyzed by serine hydroxymethyltransferase, and the second, from 3-phosphoglycerate. The latter pathway appears to be the main source of serine, especially in the CNS, where transport of L-serine and glycine across the blood–brain barrier is limited. From those observations and the discovery that mice engineered with knockouts of serine biosynthetic enzymes display an embryonic lethal phenotype, inborn errors of serine synthesis involving the three-step pathway were discovered and further characterized.

### 92.8.2 3-Phosphoglycerate Dehydrogenase Deficiency

Cases of 3-phosphoglycerate dehydrogenase (3-PGDH) deficiency (OMIM 601815) were first discovered in two siblings from consanguineous first-cousin parents who had a similar pattern of microcephaly, failure to thrive, irritability, feeding difficulties, severe developmental delay, persistently adducted thumbs, hypertonicity, and infantile-onset seizures. Brain MRI had cortical atrophy and abnormally reduced myelination. Biochemical testing demonstrated low plasma serine and glycine that normalized postprandially; the deficiency was much more pronounced in the CSF. A deficiency of 3-PGDH enzyme was demonstrated in cultured fibroblasts (281). Additional patients were subsequently reported with similar symptoms and biochemical findings. The seizure

disorder in 3-PGDH deficiency is one that is typically difficult to control with antiepileptic medications and has been described as “West syndrome” (282,283). Treatment with supplemental L-serine (500–600 mg/kg/day) and glycine (200–300 mg/kg/day) has been reported to reduce or even abolish the seizures and EEG abnormalities, although the effects on psychomotor development were much more disappointing (284). In addition, some 3-PGDH-deficient patients have demonstrated slowing of head growth with high-dose (1400 mg/kg/day) L-serine therapy, suggesting toxicity of excessive serine supplementation. One infant with 3-PGDH deficiency was diagnosed prenatally, and L-serine therapy was administered to the mother, allowing the birth of a normocephalic infant girl whose treatment was continued postnatally. Subsequently, she had normal psychomotor development and no neurologic symptoms (285). More recently, an attenuated form of 3-PGDH deficiency was described in two siblings with moderate developmental delay (IQ 50–55); absence seizures; hyperactivity; and absence of microcephaly, hypertonicity, growth failure, or brain MRI abnormalities (286). Their fasting plasma glycine levels were normal, while plasma serine levels were just below the lower limit of normal. The older sibling, however, had severely low CSF serine levels, with normal CSF glycine, and both patients responded to lower-dose L-serine supplementation (120–140 mg/kg/day) with resolution of absence seizures, though IQ did not improve. Sequence analysis of the *PHGDH* gene in the few affected families indicate that the p.V490M mutation seems to be recurrent across ethnicities; other reported mutations include p.R135W, p.V261M, p.A373T, and p.G238fsX (287). Homozygous p.G377S mutations were found in the siblings with attenuated 3-PGDH deficiency (286).

### 92.8.3 Phosphoserine Aminotransferase Deficiency

Phosphoserine aminotransferase (PSAT) deficiency (OMIM 610992) has been reported in two siblings. The older brother presented at 9 weeks of age with postnatal-onset microcephaly, intractable seizures, cerebral atrophy, hypoplastic cerebellar vermis, and delayed white-matter myelination. Plasma and CSF serine and glycine levels were below normal limits. Treatment with serine and glycine did not improve seizure control and eventually he died at 7 months of age. The younger sister was identified with the deficiency at birth because of low serine and glycine in plasma and CSF; treatment with serine was started immediately and she did not develop seizures. Brain MRI at 4 months was normal. At the last follow-up, she was 3 years old and demonstrated normal growth and development. Enzymatic analysis of PSAT was unreliable as the older sibling had normal PSAT enzymatic activity. The siblings were found to have compound

heterozygous frameshift (c.delG107) and missense (c.299A>C) mutations in the *PSAT1* gene; the missense mutation was confirmed deleterious by sequence alignment and enzymatic analysis of in vitro-expressed mutant enzyme (288). Based on the lack of neonatal symptoms but divergent outcomes of the siblings, the authors concluded that measurement of CSF serine and glycine is important in patients with neonatal seizures to allow early identification and subsequent treatment of serine biosynthetic deficiencies.

### 92.8.4 Phosphoserine Phosphatase Deficiency

Phosphoserine phosphatase (PSPH) deficiency (OMIM 172480) was identified in one patient with concurrent Williams syndrome. There was prenatal-onset microcephaly and intrauterine growth retardation, and based on the facial appearance, a diagnosis of Williams syndrome was suspected and confirmed. He demonstrated postnatal microcephaly, psychomotor delay, and failure to thrive, with gastroesophageal reflux. Plasma serine levels were reduced or low-normal while fasting and normalized following meals, while CSF serine levels were clearly low. L-serine 300 mg/kg/day was administered while allowed for slight acceleration of head growth, but head circumference remained below the third percentile and height/weight percentiles did not improve. Fibroblast PSPH enzymatic activity was 25% of normal controls and compound heterozygous p.D32N/M52T *PSPH* mutations were demonstrated (289,290). Although the *PSPH* gene and the Williams syndrome critical region are both located on chromosome 7, they are separated by 16.5 Mb and the two findings are unrelated (287).

## 92.9 DISORDERS OF AMINO ACIDS WITHOUT KNOWN CLINICAL CONSEQUENCES

A number of disorders included in the earlier editions of this text have been found to be unassociated with definable diseases and were ascertained only because children with neurologic or developmental problems were studied by amino acid screening methods. Subsequent to their description, studies of normal older siblings with the same disorder, studies of patients ascertained through newborn screening, and the inconsistent clinical findings in the index cases led inexorably to the conclusion that the biochemical abnormality was not the cause of the clinical problem. Disorders in this category include histidinemia, due to histidase deficiency (291); hyperlysinemia, due to deficiency of the bifunctional enzyme with both lysine-ketoglutarate reductase and saccharopine oxidoreductase activities (292); sarcosinemia due to sarcosine dehydrogenase deficiency (293); and cystathioninemia due to  $\gamma$ -cystathionase deficiency (117).

### Biography

**Raymond Y Wang** is a member of the Pediatric Subspecialty Faculty in the Division of Metabolic Disorders at the CHOC Children's Hospital in Orange, California. He attended medical school at the University of California–Los Angeles, then completed his residency in pediatrics and medical genetics at the University of California–Los Angeles/Cedars-Sinai Medical Center. He went on to complete a fellowship in clinical biochemical genetics at Cedars-Sinai Medical Center. Among his research interests are studying the clinical outcomes of infants prospectively identified via newborn screening to have inborn errors of metabolism. One such disorder currently under investigation is short-chain acyl-CoA dehydrogenase deficiency. Another initiative he has been actively involved with is delineating potential strategies for follow-up evaluations and treatment of lysosomal storage disorders identified via newborn screening.

### 93.1 INTRODUCTION

Inborn errors of carbohydrate metabolism discussed in this chapter include disaccharidase deficiencies, disorders of monosaccharide metabolism, glycogen storage diseases (GSDs), and gluconeogenic disorders. Additional information may be sought in *The Online Metabolic and Molecular Basis of Inherited Disease* by Scriver and coworkers (1).

### 93.2 DISACCHARIDASE DEFICIENCIES

The major sources of dietary carbohydrate in humans are starch and the disaccharides lactose and sucrose. In adults, starch constitutes 60% of the carbohydrate ingested, however, in newborns and young infants, the primary carbohydrate is lactose (milk sugar). Sucrose consumption varies widely with the choice of infant formula and other eating habits. The normal digestive process involves the splitting of disaccharides by intestinal hydrolytic enzymes (lactase, sucrase, isomaltase, and maltase) into monosaccharides before absorption (Figure 93-1).

Defective intestinal digestion of dietary sugars leads to symptoms of flatulence, abdominal cramps, diarrhea, and perianal irritation. Levels of enzymes involved in the hydrolysis of disaccharides may be depressed on either a genetic or an acquired basis. The latter situation results from damage to the brush border cells of the small intestine, consequent to infection or other injuries. When enzymatic hydrolysis is impaired, ingested disaccharide accumulates and provides a growth medium for intestinal bacteria that produce carbon dioxide, hydrogen gas, and organic acids. The stools tend to be sour, foamy, loose, and watery with an acidic pH. A diagnosis of disaccharidase deficiency may be suspected from the history of symptoms developing in association with the ingestion of a particular sugar and a laboratory finding of disaccharides in the urine. Direct confirmation may

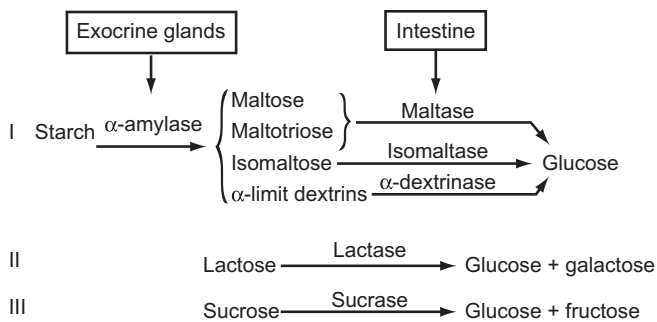

be obtained by enzyme assays in peroral small bowel biopsy. Indirect confirmation of the diagnosis can be made by a disaccharide tolerance test. Disaccharidase deficiency is suggested if the blood glucose curve is flat upon ingestion of the suspect disaccharide and the breath hydrogen concentration is increased. Genetic testing provides an accurate method for determining disaccharidase deficiency (2).

#### 93.2.1 Lactase Deficiency

Congenital lactase deficiency is a rare autosomal recessive inherited disorder that appears to have a higher frequency in the Finnish population (3). Affected infants present with a severe gastrointestinal problem characterized by watery diarrhea as soon as milk or lactose-containing foods are introduced, then dehydration, acidosis, and weight loss follow.

Late-onset (adult-type) lactase deficiency, also known as hypolactasia or lactase nonpersistence, differs from that encountered in infants at the age of onset, clinical severity and molecular defect (4). Symptoms usually do not occur until adult life but occasionally may start at an earlier age. This form of lactase deficiency is common in individuals from Mediterranean countries, African-Americans, Asians, Native Americans and Eskimos (5). Treatment for patients with lactase deficiency usually consists of a diet free of lactose or inclusion of exogenous lactase. In infants, a lactose-hydrolyzed human milk has been used (6). Treatment usually results in a rapid clinical response.

On the molecular level, both adult-type hypolactasia and congenital lactase deficiency stem from variants affecting the lactase gene localized on chromosomes 2q21–22; however, the molecular mechanisms causing the two disorders are different. Congenital lactase deficiency appears to be caused by mutations that directly affect the lactase polypeptide (7). In a study of 32 Finnish patients with congenital lactase deficiency, five mutations in the lactase gene were identified, the most prevalent of

**FIGURE 93-1** Digestion of carbohydrates.

which was the nonsense mutation p.Cys1390X in exon 9 accounting for 90% of affected alleles (4). In adults with hypolactasia, the lactase enzyme appears identical to that in adults with higher lactase levels, as is the lactase gene sequence. Evidence suggests that the variation of lactase level in adults is controlled by polymorphic elements cis-acting to the lactase gene, which necessitate transcription factor binding (7,8). In the normal process of human development lactase activity declines. However, mutations have resulted in lactase persistence, which is inherited as an autosomal dominant condition. Often attributed to evolutionary circumstances, the frequency of these mutations appears to be different in various populations (8,9). Unlike many factors that result in lactase nonpersistence, lactase persistence relies almost singly on the continuation of synthesis. The biological simplicity of lactase persistence may have led to the observed evolutionary variability (10).

### 93.2.2 Sucrase–Isomaltase Deficiency

The mode of inheritance of this condition appears to be autosomal recessive. An incidence of 0.2% has been reported for North Americans and 10% for Greenland Eskimos (11). Clinical manifestations tend to be more severe in younger children and depend on the amount of ingested sucrose, which usually comes from fruits and sweetened foods. The disease is caused by mutations in the gene coding for sucrase–isomaltase. Different mutations lead to either defects in the intracellular processing of the enzyme or functionally alter the enzyme. The degree of severity is a spectrum from complete absence of sucrase to trace levels of operating isomaltase (10). Studies have shown sucrase–isomaltase deficiency can also be noninvasively determined by <sup>13</sup>C-sucrose-labeled breath tests (12). Effective treatment for sucrase–isomaltase deficiency includes Sucraid (sacrosidase) enzyme replacement therapy and a diet with severely limited sucrose intake (13).

## 93.3 GLUCOSE–GALACTOSE MALABSORPTION

This is a rare disorder in which acute, profuse, watery diarrhea develops in newborn infants following initial feeding. Intestinal disaccharidase activities are normal.

Fructose is absorbed normally, but glucose and galactose are not. There is no significant rise in blood glucose levels following an oral glucose–galactose tolerance test. However, a breath hydrogen test reveals glucose–galactose malabsorption (14). The stool usually contains large amounts of reducing sugars (>2g%). Diarrhea stops when free glucose and galactose are removed from the diet. Nephrocalcinosis and nephrolithiasis have been reported. All patients have mild defects in renal tubular reabsorption of glucose. The basic defect is in the transport protein (Na<sup>+</sup>/glucose cotransporter) localized in the brush border membrane of the small intestinal epithelial cells (15). The protein is encoded by the *SGLT1* gene that is localized on chromosome 22q. Pedigree analysis of a consanguineous Swedish family going back 10 generations suggests autosomal recessive inheritance (16). More than 40 mutations have been identified (17). Certain mutations appear to be recurrent in specific populations like the Old Order Amish, suggesting the role of founder effect (18). A novel homozygous nonsense mutation p.Arg267X that results in hypercalcemia, nephrocalcinosis and proximal tubular dysfunction has been reported (19).

### 93.3.1 Glucose Transport Defects

Each of the 14 glucose transporter proteins that have been identified to date targets specific tissues in order to facilitate the diffusion of glucose across the plasma membrane (20). The genes for these transporter proteins have also been localized (21). Of known clinical significance are GLUT1, GLUT2 and GLUT10.

GLUT1 aids in the diffusion of glucose across the blood–brain barrier. The classic presentation for GLUT1 deficiency includes epilepsy, developmental delay, acquired microcephaly, spasticity, and ataxia. The expanded phenotype includes paroxysmal movement disorders and atypical childhood absence epilepsy, although there has been one case without epilepsy (22). The accompanying severe seizure disorder can be partially or fully remedied with a ketogenic diet (23). Low CSF glucose values (relative to blood glucose) and low CSF lactate levels are virtually diagnostic (24,25). The gene for GLUT1 is located on chromosome 1p.34.2. GLUT1 defects are normally inherited in an autosomal dominant manner, with de novo mutations producing haploinsufficiency and conferring symptomatic heterozygosity, but recent studies have shown that the defects may also be inherited in an autosomal recessive manner (26,27). Molecular analyses have identified a wide spectrum of heterozygous mutations, including nonsense, missense, insertion, deletion, splice-site mutations and microdeletions (23). More than 200 cases have been identified (28).

GLUT2 defects cause Fanconi–Bickel syndrome. More than 100 cases have been reported, and 34 different mutations have been identified, with none of them being

particularly frequent (29). It is characterized by proximal renal tubular dysfunction, as well as hepatic dysfunction, which result in glycogen accumulation in the liver. The affected patients present with rickets, hepatomegaly, and growth failure associated with impaired glucose and galactose tolerance, increased renal clearance of glucose, amino acids, protein, phosphate, and uric acid as well as glycogen accumulation in the liver (21). Due to the latter, Fanconi–Bickel syndrome has also been classified as a type of glycogen storage disease (see glycogen storage disease type XI). GLUT3 transports glucose in human neural, brain, and muscular tissues (30). GLUT4 is the insulin-responsive glucose transporter involved in the signaling pathway that regulates glucose metabolism in muscle cells and adipocytes, and the gene is localized in 17p. States of insulin resistance such as in obesity, type II diabetes, and long-term fasting, trigger a drop in GLUT4 transcription and expression in adipocytes (31). GLUT5 has been identified as a key molecule in fructose transportation and GLUT9 has been classified as a urate transporter (20).

GLUT10, instead of transporting glucose like the other GLUT transporters, functions as a mitochondrial transporter for the oxidized form of vitamin C (32). Loss of GLUT10 function causes arterial tortuosity syndrome, an autosomal recessive disorder characterized by tortuosity, elongation, stenosis, and aneurysm formation in the major arteries (33). It is expected that we will learn more about the roles of other glucose transporters in carbohydrate metabolism through research.

## 93.4 DISORDERS OF GALACTOSE METABOLISM

### 93.4.1 Galactose Metabolism

Galactose, a component of lactose, is an important nutrient for newborn infants and young children. In human breast milk, the lactose content is about 7 g/dL, and in cow's milk the concentration is approximately 5 g/dL. In the newborn infant, lactose may provide as much as 40% of the caloric intake but only 3–4% in the adult due to proportionally lower milk intake. Galactose is also a constituent of many glycoproteins, glycolipids, and mucopolysaccharides.

The principal pathway for the metabolism of galactose has been designated as the Leloir pathway (Figure 93-2). Galactose is phosphorylated to galactose-1-phosphate by the enzyme galactokinase. Galactose-1-phosphate is exchanged for the glucose-1-phosphate moiety of uridine diphosphate glucose (UDPG) to form uridine diphosphate galactose (UDPGal) by galactose-1-phosphate uridyl transferase (transferase or GALT). The glucose-1-phosphate released leads into the glucose pathway. The UDPGal formed is converted to UDPG by the enzyme UDPGal-4-epimerase (epimerase). The sum of these three enzymatic reactions involving galactokinase, transferase, and epimerase is

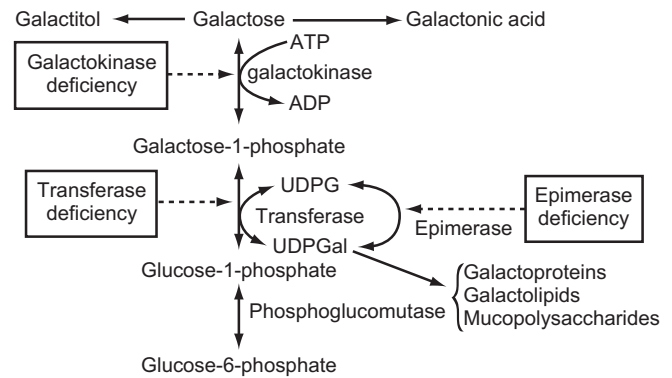

FIGURE 93-2 Pathways of galactose metabolism.

Galactose + adenosine triphosphate (ATP) = Glucose-1-phosphate + adenosine diphosphate (ADP).

UDPGal is also used for the synthesis of galactose-containing complex carbohydrates. A small amount of galactose is converted to galactitol by aldose reductase and to galactonic acid by galactose dehydrogenase.

These three galactose enzymes in the major pathway are widely distributed in tissues, including erythrocytes, leukocytes, liver, kidney, brain, cultured skin fibroblasts, chorionic villi, and amniotic fluid cells. The gene loci in humans for galactokinase, transferase, and epimerase are on chromosomes 17, 9, and 1, respectively (34–36).

Deficiency in the activity of each of the three enzymes results in metabolic disorders known as galactokinase deficiency, galactose-1-phosphate uridyl transferase deficiency (galactosemia), and UDPgalactose-4-epimerase deficiency. All three disorders can be identified by newborn screening based on increased amounts of galactose or galactose-1-phosphate in the blood spots (Guthrie cards), provided that there is normal amount of lactose intake in the newborn's formula or breast feedings. The identification of the specific defect is based on enzyme assays in erythrocytes, providing that the newborn did not receive a blood transfusion before the collection of the blood sample. Often, the Beutler spot test has been employed by newborn screening laboratories for the detection of the transferase defect (37). Some screening laboratories employ automated transferase activity analysis. As of recently, all three galactose enzymes can now be simultaneously analyzed through a novel multiplex enzyme assay utilizing ultraperformance liquid chromatography–tandem mass spectrometry (UPLC–MS/MS) (38).

### 93.4.2 Galactokinase Deficiency

**93.4.2.1 Clinical Aspects.** Galactokinase deficiency was first reported by Gitzelmann (39). The patient was a 42-year-old man originally described as having galactose diabetes at 9 years of age. Additional patients were reported subsequently. The major clinical manifestations

are cataracts and pseudotumor cerebri, both appearing early in life. In contrast to the transferase defect, hepatomegaly, jaundice and mental retardation are not usually the features of this disorder, yet isolated reports of one or more of these findings have been made in patients with galactokinase deficiency. It has been suggested that carriers of galactokinase deficiency may be at risk for presenile cataracts.

**93.4.2.2 Biochemical Aspects.** Ingestion of lactose-containing diets will raise blood galactose concentrations to values as high as 100mg/dL in patients with galactokinase deficiency (40). As a consequence, galactose appears in the urine. Galactitol and galactonic acid are produced in increased amounts owing to diversion of galactose into these secondary pathways. It is thought that the accumulation of galactitol is the cause of cataract formation and cerebral edema. In contrast to classic galactosemia (transferase deficiency), aminoaciduria and proteinuria are usually absent. The diagnosis of galactokinase deficiency can be confirmed by measurement of the enzyme activity in erythrocytes. One should be aware that erythrocyte galactokinase activity is much higher in newborns and decreases with age. The enzyme is not stable in erythrocytes stored at room temperature, but it is stable in washed red blood cells frozen for more than 1 week.

**93.4.2.3 Treatment.** Early treatment is important to prevent progression of cataract formation. Treatment consists of exclusion of lactose and other sources of galactose from the diet.

**93.4.2.4 Genetic Aspects.** Galactokinase deficiency is transmitted as an autosomal recessive trait. Parents of affected children exhibit intermediate values of erythrocyte galactokinase activity. Based upon the results of newborn screening programs, the frequency of occurrence has been estimated at about 1:250,000. A galactokinase variant with lower than normal activity (Philadelphia) has been described among asymptomatic black Americans and black Africans (41,42). Over 30 mutations have been identified among patients with galactokinase deficiency, most of them being private mutations. Only three GALK1 mutations have been found to be frequent in certain populations: p.Pro28Thr (a founder mutation in the Romani population); p.Gln382X (occurs frequently in the Costa Rican population); and p.Ala198Val (named the “Osaka variant,” occurs in the Japanese and Korean populations) (43,44). The carrier rate for galactokinase deficiency in the Romani population, particularly those from the former Yugoslavia and present-day Bosnia and Herzegovina, is about 5%. Galactokinase activity is present in cultured amniotic fluid cells; this provides a means for prenatal diagnosis in addition to molecular testing. Families at risk should receive genetic counseling, and pregnant mothers at risk should be advised to restrict intake of lactose and other sources of galactose to protect an affected fetus. Newborn screening and a preemptive adoption of the galactose-free diet is highly

recommended for children whose parents carry the galactokinase deficiency gene, especially those of the Romani population (45).

### 93.4.3 Galactose-1-Phosphate Uridyl Transferase Deficiency (Galactosemia)

**93.4.3.1 Clinical Aspects.** Galactosemia was probably first described in 1908 by von Reuss (46), but it was not until 1956 that Kalckar and his associates (47) established the defect in activity of the enzyme galactose-1-phosphate uridyl transferase. The deficiency is polymorphic with the most common variant, the Duarte allele, differing significantly in prognosis and clinical outcome from classic galactosemia (48). In the classic form, untreated patients show distinctive manifestations early in life. The infant appears normal at birth, and symptoms usually do not develop until milk feedings are given. Food may be refused; vomiting is common, and diarrhea occurs occasionally. Other manifestations include lethargy, hypotonia, jaundice, hepatomegaly, and susceptibility to infection with Gram-negative organisms. In untreated patients, cataracts become evident, and physical and mental retardation occur. The clinical course of many infants is fulminant, and death occurs early from inanition, infection and hepatic failure. In some patients, the course is much milder and may even escape early detection. Late clinical manifestations have been reported in both untreated and treated galactosemia patients (49). These include hypergonadotropic hypogonadism in about 80% of the affected women, speech defects in about half, and, to a lesser extent, neurologic sequelae (50). Although many female patients develop ovarian hypofunction, gonadal function in adult males appears to be normal. It appears that small amounts of transferase activity in some female patients with galactosemia may preserve normal gonadal function; those with the p.Ser135Leu genotype are shown to have a lower likelihood of ovarian dysfunction (50,51). Galactosemic men and women have had normal offspring (52,53). Difficulties in school are frequently encountered.

Contrastingly, those presenting with the heterozygous Duarte variant (D/G) of galactosemia typically have 25% of normal GALT enzyme activity, little to no symptoms, slightly elevated metabolites and no need for intervention (54). Other variants, as they typically have a certain level of enzyme activity, are similar in clinical presentation and usually require no intervention.

**93.4.3.2 Biochemical Aspects.** Classic galactosemia (G/G) is defined as GALT activity below 5% and gal-1-P buildup greater than 20mg/dL accompanying with severe mutations, although a few less serious mutations may also be included (48). Galactosemia may be suspected on clinical grounds, but laboratory confirmation is essential. Diagnostic tests, which are based on response to galactose ingestion, should not be employed because they are hazardous for the infant patients. Direct enzyme

assay using erythrocytes can be readily carried out to confirm the diagnosis. On a galactose-containing diet, affected individuals excrete large amounts of galactose, galactitol, and galactonic acid in the urine. Gross generalized aminoaciduria and proteinuria are also evident. The erythrocyte galactose-1-phosphate level is elevated. It is believed that this compound produces hepatic damage, whereas galactitol accounts for the formation of cataracts. Decreased levels of UDPGal, a product of the transferase reaction, have been observed in erythrocytes, cultured skin fibroblasts, and liver autopsy samples of patients with galactosemia with complete absence of erythrocyte transferase activity (55). On the other hand, patients with small but detectable erythrocyte transferase activity were found to have normal levels of UDPGal. The absolute values of UDPG and UDPGal for erythrocytes were different depending on the method used for analysis (56). However, the relative decrease of UDPGal levels in erythrocytes and cultured skin fibroblasts of galactosemia patients is a consistent finding (57). Molecular genetic testing, in addition to confirming galactosemia, helps identify which variant of the disease is present. This is especially important in differentiating the Duarte allele (D1) from the Los Angeles allele (D2), as they have the same missense mutation (58).

There are many reliable methods for the measurement of erythrocyte transferase activity; affected individuals exhibit either little or no activity in their red blood cells. Blood transfusions in patients interfere with the interpretation of the test because of the transferase activity present in the donor cells. Under this circumstance, studies on both parents to determine heterozygosity can be helpful in reaching a presumptive diagnosis. Neonatal screenings for galactosemia have been carried out in many countries effectively, reducing morbidity and mortality. Methods depend on the measurement of galactose and/or galactose-1-phosphate by microbiologic assays (59), by galactose dehydrogenase (60), by measurement of transferase activity with a fluorescent spot test (61), or modified by automated fluorescent analysis. The latter is based on enzyme coupling reactions through phosphoglucomutase and glucose-6-phosphate dehydrogenase in the production of NADPH. The assay measuring free galactose will detect both galactokinase and transferase defects, whereas the enzyme assay is limited to recognition of the transferase defect. When the screening method incorporates both galactose dehydrogenase and alkaline phosphatase for the measurement of galactose-1-phosphate, an elevated galactose-1-phosphate level will be found not only in patients with transferase deficiency but also in epimerase deficiency. A novel method utilizing high-performance liquid chromatography with nonradioactive UV efficiently and accurately detects galactose-1-phosphate uridyltransferase in erythrocytes (62).

Aside from classic galactosemia, variant galactosemia includes any mutation that causes the GALT enzyme to function partially. The Duarte homozygote has 50% of

normal transferase activity similar to carriers for galactosemia but with a different electrophoretic pattern. Owing to the high frequency of the Duarte variant, the Duarte-galactosemia compound heterozygotes (D/G) with about 25% of normal activity are often identified on confirmation of the neonatal screening programs for galactosemia, which utilizes the transferase assays. Some of the values are near the low-end levels for affected galactosemia patients. It is not proper to rely solely on molecular mutation data for the identification of Duarte-galactosemia compound heterozygotes because the galactosemia allele can have both classic galactosemia and Duarte mutations (63). Identification by biochemical means (both quantitative activity measurement and electrophoretic pattern) is recommended. For genetically heterogenous patients, especially those with less common genotypes, the liquid chromatography–tandem mass spectrometry-based assay for GALT enzyme activity effectively produces quantitative measurements (64).

**93.4.3.3 Treatment.** Treatment is directed toward minimizing the accumulation of galactose and its metabolites in body tissues by excluding milk and milk-containing products from the diet. Various milk substitutes are available (casein hydrolysates, soybean formulas). Although a galactose-free diet is the basis of treatment, supplementary measures are often required in the neonate to correct secondary manifestations, such as hyperbilirubinaemia, hypoprothrombinaemia, sepsis with Gram-negative organisms, and anemia. The infections often respond poorly to antibiotic therapy unless restriction of galactose is also carried out. The effects of dietary treatment are dramatic, with immediate reversal of the acute manifestations. Galactose restriction, with adequate calcium supplementation, is compatible with good general health and normal patterns of physical development. As a group, patients treated at infancy can achieve low to normal intelligence scores, but in spite of dietary restriction of lactose, many patients still have learning and/or behavioral problems in later life. A recent study showed that children with the Duarte variant need not follow a restrictive diet because, although they present with elevated levels of several galactose metabolites, they have normal levels of erythrocyte galactose-1-phosphate (65).

**93.4.3.4 Genetic Aspects.** Galactosemia has been found in all races, but the incidence appears to be higher among Caucasians than among Asians. The frequency of classic galactosemia based on newborn screening in the United States is approximately 1:47,000 (66). The disorder is transmitted as an autosomal recessive trait.

Several biochemical variants of erythrocyte transferase have been described. Some have been associated with disease, and others have not. The most common and understood variant of transferase-deficiency galactosemia is attributed to the Duarte allele (D<sub>1</sub>), which is allelic to the less-frequent Los Angeles allele (D<sub>2</sub>) (61). Both variant enzymes have identical electrophoretic

patterns, but they differ in the extent of their erythrocyte activities. The Duarte variant exhibits low activity, with homozygotes having about half-normal activity, while the Los Angeles variant has a slightly higher than normal activity. The Duarte and Los Angeles variants have the same molecular mutation in cDNA p.Asn314Asp, and the difference in activity is attributed to intron changes (58). The Los Angeles variant carries a silent c.1721C>T mutation in exon 7. Both Duarte and Los Angeles variants have an extended sequence of 28 adenine nucleotides in intron 10, instead of 17 adenine nucleotides in the corresponding sequence of the normal allele. The frequency of Duarte heterozygosity is about 12–13% in the white population. A third asymptomatic transferase variant designated as the Berne variant exhibits decreased activity and slower electrophoretic mobility than normal (67).

More than 230 mutations have been identified that are associated with transferase deficiency, and this list continues to grow (68). Among white patients, the most common mutation causing classic galactosemia is p.Gln188Arg and the second is p.Lys285Asn (69,70). The p.Gln188Arg mutation is associated with complete absence of transferase activity and poor outcome (71,72). The allele is thought to be present in about 60% of the white North American population (61). P.Ser135Leu is seen in 48% of black patients with classic galactosemia and is associated with milder clinical presentations (51). Another mutation, one which seems to appear only in black patients, is p.Phe171Ser (73). The Ashkenazi population has a high carrier frequency (1:127; 0.79%) of a rare deletion mutation (68). Other variants with mild clinical manifestations, detectable transferase activity, and different molecular mutations have also been reported (74,75).

Prenatal diagnosis of galactosemia is feasible and has been performed successfully in a number of instances by measuring transferase activity in cultured amniocytes and chorionic villi, by galactitol concentration in amniotic fluid, or more recently, by molecular mutation analysis.

#### 93.4.4 Uridine Diphosphate Galactose-4-Epimerase Deficiency

Epimerase deficiency can be classified arbitrarily into two forms: severe and benign. The severe form can be referred to as generalized epimerase deficiency due to insufficient enzyme activity in all tissues. The benign form can be characterized as either peripheral or intermediate deficiency, the former referring to low enzyme activity only in erythrocytes and the latter referring to epimerase activity below 50% of normal levels in all other cells in addition to deficient activity in erythrocytes (76). Inheritance for both types is autosomal recessive. The severe form is rare, with only a few documented cases (77–79). The clinical symptoms are somewhat

similar to those in classic galactosemia: jaundice, weight loss, vomiting, hypotonia, and hepatomegaly. Dietary treatment with limitation on galactose intake has been tried, but the outcome was uncertain.

The benign form of epimerase deficiency is more common and does not appear to be associated with any clinical problems. The patients are usually identified through neonatal screening for galactosemia because of increased erythrocyte galactose-1-phosphate levels (20–50 mg/dL) and a small increase of free blood galactose. No treatment appears to be required. The decrease in epimerase activity in the benign form is confined to the red cells and white cells. Normal activity has been found in liver and cultured skin fibroblasts (80). The deficiency is attributed to the presence of an unstable variant enzyme requiring higher NAD concentration for maximum activity. In the United States, the frequency of erythrocyte epimerase deficiency appears to be higher among blacks (81).

The cDNA for epimerase was cloned and the gene was localized to chromosome 1p36–p35 (82). Several mutations have been identified among patients with epimerase deficiency (83). The pathogenesis of p.Val95Met mutation in the severe form of epimerase deficiency has been explored in the yeast expression system, and accumulation of galactose-1-phosphate may account for the toxicity (84).

## 93.5 DISORDERS OF FRUCTOSE METABOLISM

### 93.5.1 Fructose Metabolism

Fructose is a monosaccharide found in honey, fruits, vegetables, and plants. In combination with glucose, it forms the disaccharide sucrose. It also exists in a number of oligosaccharides, such as raffinose (a trisaccharide) and stachyose (a tetrasaccharide). Stachyose is found abundantly in legumes. Ingested sucrose is hydrolyzed by intestinal sucrase to glucose and fructose. The oligosaccharides raffinose and stachyose, which also contain galactose and glucose, are not digested in humans.

The liver plays a dominant role in the metabolism of fructose; other organs metabolize fructose but to a lesser extent (Figure 93-3). The overall process results in conversion of the sugar to glycolytic intermediates, leading to the formation of either glucose or lactic acid. In the liver, fructose is phosphorylated to fructose-1-phosphate (F-1-P) in the presence of fructokinase. The enzyme is also present in kidney and in intestinal mucosa. Fructokinase is not present in muscle, adipose tissue and blood cells, and in these tissues, fructose is phosphorylated to fructose-6-phosphate by hexokinase. In the liver, F-1-P is further metabolized to D-glyceraldehyde and dihydroxyacetone phosphate by F-1-P aldolase or aldolase B. Aldolase B differs from aldolase A and C in that the latter isozymes act principally on fructose-1,6-diphosphate. In the seminal vesicles, the lens of the eye, and peripheral

**FIGURE 93-3** Pathways of fructose metabolism.

nerves, fructose can be metabolized to sorbitol. In normal subjects, *in vivo* radioisotope studies have shown that fructose is converted to glucose solely by way of F-1-P (85). Sorbitol does not appear to be an intermediate. In two patients with hereditary fructose intolerance (HFI) due to F-1-P aldolase deficiency, it was estimated that 12–20% of fructose was metabolized by way of fructose-6-phosphate.

In humans, deficiencies in hepatic fructokinase and F-1-P aldolase have been described. Inactivity of fructokinase is responsible for essential fructosuria (fructosemia), whereas deficiency of F-1-P aldolase results in HFI. Fructose-1,6-diphosphatase deficiency is sometimes included among the disorders of fructose metabolism, but it seems more appropriate to list it as one of the gluconeogenic disorders described later in this chapter.

### 93.5.2 Essential Fructosuria

The incidence of this benign condition is estimated as 1:130,000 in the general population (86). However, essential fructosuria usually causes no symptoms and the incidence may be somewhat higher. Transmission follows an autosomal recessive pattern. The genetic defect is a deficiency of hepatic fructokinase. Ingested fructose is not well metabolized by the liver and reaches to high levels in the blood with overflow into the urine. The presence of the sugar in the urine can readily be demonstrated. No treatment is necessary.

### 93.5.3 Hereditary Fructose Intolerance

**93.5.3.1 Clinical Aspects.** The clinical manifestation in individuals with HFI may vary with the age at which fructose or sucrose is introduced into the diet and with

the quantity of sugar ingested. In some individuals, symptoms are subtle. In infants, ingestion of fructose may produce findings similar to those found in galactosemia and seizures. Because many formulas contain sucrose, the opportunities of an affected infant for exposure to fructose are increased accordingly. In older children and in adults with HFI, ingestion of fructose, sucrose or sorbitol causes abdominal pain and lowers the blood glucose level precipitously. Pallor, vomiting, sweating, and even coma may occur. It is typical for these individuals to develop a strong aversion for all sweets and to be free of dental caries.

**93.5.3.2 Biochemical Aspects.** The biochemical defect in HFI is a deficiency of liver F-1-P aldolase (aldolase B). Enzyme activity is usually less than 10% of normal when F-1-P is used as the assay substrate, and it is between 10 and 50% of normal when fructose-1,6-diphosphate is the substrate. The enzyme deficiency can also be demonstrated in intestinal mucosa. Blood cells cannot be used for diagnosis because the enzyme is not present in leukocytes or erythrocytes.

Whereas the diagnosis of HFI can be suspected on clinical grounds, laboratory confirmation is essential. Untreated patients ingesting fructose in their diet may excrete large amounts of this sugar in their urine and also show a gross generalized aminoaciduria. A fructose tolerance test, administered with caution, can be a useful first step in facilitating diagnosis. Assay of the enzyme requires either a biopsy sample of liver or intestinal mucosa. Administration of fructose, either orally or parenterally, is followed by a fall in the blood glucose level and serum inorganic phosphate (presumably due to its utilization in the formation of F-1-P). The uric acid level in blood rises from rapid degradation of purine nucleotides to uric acid. The hypoglycemia is related to

inhibition of glycogenolysis by F-1-P. Molecular diagnosis is possible (see section on genetic aspects).

HFI may be confused biochemically with tyrosinosis in early infancy insofar as elevation of blood tyrosine and methionine levels have been observed in some cases, presumably because of liver damage. The gross generalized aminoaciduria is akin to that seen in galactosemia patients and may result from toxic action of F-1-P on the proximal renal tubules. Observation of fructosuria, however, serves to distinguish HFI from galactosemia or tyrosinosis.

**93.5.3.3 Treatment.** The clinical manifestations in young infants with HFI may be severe, and prompt elimination of fructose and sorbitol from the diet is important. Major sources of fructose include cane sugar, honey, fruits, and formula using sucrose as the source of carbohydrate. The prognosis for treated patients is good. Liver and kidney damage is reversed, and neurologic residuals are uncommon. The use of fructose infusion as a source of calories in hospitalized adult patients must be approached with caution until it is known that the patient does not have HFI.

**93.5.3.4 Genetic Aspects.** The frequency of occurrence of HFI in the general population is not known because many patients with HFI may not be recognized. An incidence of 1:20,000 has been reported for Switzerland (87). The defect is inherited as an autosomal recessive trait. Heterozygote detection, which has now been accomplished through DNA testing and P-magnetic resonance spectroscopy, was previously complicated by relative inaccessibility of tissue for enzyme assay and the inability to differentiate normals from heterozygotes by parenteral loading with fructose (86).

The gene for aldolase B is located on chromosome 9q21.3–q22.2 and consists of nine exons that code for 363 amino acids (88). At least 40 mutations (e.g. missense, nonsense, deletions, splice-site) were identified among HFI patients, two of which are upstream of the protein-coding region (89). Three mutations: p.Ala149Pro, p.Ala174Asp, and p.Asn334Lys account for 87% of alleles in the European HFI population and for 68% in the North American population. One recently discovered mutation, IVS1+1G>C, has a higher allele frequency (6%) in African-American and Hispanic HFI patients (89). A patient with partial activity was found to have a nonsense mutation in exon 3 and a missense mutation in exon 5 (90). A study in Napoli, Italy, identified six patients (homozygous p.Ala150Pro and p.Ala175Asp) with the same deletion at exon 5 (91). Therefore, it is possible to use DNA analysis as a way to confirm the diagnosis instead of enzyme assay in liver biopsy samples (92).

## 93.6 DISORDERS OF PENTOSE METABOLISM

It is well recognized that about 90% of glucose metabolism in animal tissues is through the glycolytic pathway

and the remaining 10% through the hexose monophosphate pathway. The hexose monophosphate shunt leads to the formation of pentoses as well as providing NADPH (Figure 93-4). One of the metabolites, ribose-5-phosphate, is used in the biosynthesis of ribonucleotides and deoxyribonucleotides. Through the transketolase and transaldolase reactions, the pentose phosphates can be converted back to fructose-6-phosphate and glucose-6-phosphate. Sugar alcohols (e.g. erythritol, ribitol, arabitol) are formed through the respective dehydrogenases. The X-linked glucose-6-phosphate dehydrogenase deficiency, the most prominent genetic disorder in humans, is a well-known cause of hemolytic anemia. The prevalence of the deficiency, given the enzyme is present at reduced levels and not completely absent (incompatible with life), is attributed to the mutation's role in protecting against malaria (93). The mutation has also been linked to prevention of coronary heart disease (93,94). The congenital abnormalities in pentose metabolism resulting in clinical manifestations have been recently uncovered and include transaldolase deficiency and ribose-5-phosphate isomerase deficiency.

### 93.6.1 Transaldolase Deficiency

The first case of transaldolase (TALDO) deficiency was described by Verhoeven et al. in 2001 in which a female infant was born from consanguineous Turkish parents (95). The patient presented with hepatosplenomegaly in her early life. Biochemical abnormalities reveal elevated levels of arabitol, ribitol, and erythritol in the urine. Liver function enzymes and intellectual development were normal. At 10 years of age, the patient was found to have a cirrhotic liver, height at the 10th percentile and weight for height at the 2nd percentile, persistent thrombocytopenia, and elevated sugar alcohols, as previously found in both urine and plasma. Indirect assays of transketolase and transaldolase in cultured lymphoblast homogenates pointed out the defect in the transaldolase reaction with absence of fructose-6-phosphate and glucose-6-phosphate from the incubations. Molecular study revealed a homozygous deletion of 3 bp of the transaldolase gene from this patient. A second case was a neonate who died from severe hepatopathy and cardiomyopathy at the age of 18 days (96). At this time, only 10 affected individuals from six families have been identified, all of whom presented with liver disease (97). The disease has broad phenotypic heterogeneity, ranging from fetal hydrops to slow-progressing liver cirrhosis. In all 10 patients, the leading symptoms reported during the neonatal period were bleeding tendencies with thrombocytopenia, abnormal liver function tests, hepatosplenomegaly, hemolytic anemia, and dysmorphic features (down-slanting palpebral fissures, low-set ears, and cutis laxa). Interestingly, mental development and motor development were normal in majority of the patients who were assessed (three patients died before 6 months of age). The biochemical

**FIGURE 93-4** The pentose pathways. Erythro, erythrose; Erythro-4-P, erythrose-4-phosphate; Fru-6-P, fructose-6-phosphate; Glc-6-P, glucose-6-phosphate; Glycer-3-P, glyceraldehydes-3-phosphate; 6-PGA, 6-phosphogluconic acid; Ribo, ribose; Ribo-5-P, ribose-5-phosphate; Ribu, ribulose; Ribu-5-P, ribulose-5-phosphate; rk, ribokinase; rpe, ribulose-5-phosphate epimerase; rpi, ribose-5-phosphate isomerase; Sedohep-7-P, sedoheptulose-7-phosphate; ta, transaldolase; tk, transketolase; xd, xylitol dehydrogenase; xk, xylulokinase; Xylol, xylitol; Xylu, xylulose; Xylu-5-P, xylulose-5-phosphate. (Modified from Huck, J. H. J.; Struys, E. A.; Verhoeven, N. M., et al. *Profiling of Pentose Phosphate Pathway Intermediates in Blood Spots by Tandem Mass Spectrometry: Application to Transaldolase Deficiency*. Clin. Chem. **2003**, 49, 1375–1380.)

profiles of all affected patients were similar: each included elevated urine erythritol, arabitol, ribitol, sedoheptitol, perseitol, sedoheptulose, mannoheptulose, and sedoheptulose-7P (97). Another hallmark metabolite, erythronic acid, was recently identified by urine NMR spectroscopy (98). Diagnostic confirmation can be completed by sequence analysis of the transaldolase gene as well as by measurement of TALDO activity in fibroblasts, lymphoblasts, or liver tissue.

### 93.6.2 Ribose-5-Phosphate Isomerase Deficiency

The first and only known case to date of ribose-5-phosphate isomerase (RPI) deficiency was reported and detailed by Huck et al. (99). The affected male patient had psychomotor retardation from early childhood, developing epilepsy at 4 years of age. Thereafter, a slow neurologic regression developed with prominent cerebellar ataxia, some spasticity, optic atrophy, and a mild sensorimotor neuropathy. Magnetic resonance imaging of the brain at ages 11 years and 14 years showed extensive abnormalities of the cerebral white matter. Proton magnetic resonance spectroscopy of the brain revealed elevated levels of ribitol and D-arabitol. These pentitols were also increased in urine and plasma, similar to what is found in patients with transaldolase deficiency.

Enzyme assays in cultured fibroblast homogenates showed deficient activity in ribose-5-phosphate isomerase. Molecular analysis showed a single base-pair deletion and a single transition.

### 93.6.3 Essential Pentosuria

Essential pentosuria is a benign disorder encountered principally in Ashkenazi Jews and is inherited as an autosomal recessive trait. The urine contains L-xylulose, which is excreted in increased amounts (1–4g daily) because of a block in the conversion of L-xylulose to xylitol due to xylitol dehydrogenase deficiency (100). The condition is usually discovered accidentally, and no treatment is required.

## 93.7 GLYCOGEN STORAGE DISEASES

### 93.7.1 Glycogen Metabolism

Glycogen is the principal storage form of carbohydrate in animal cells; it is present in virtually every type of tissue. Glycogen is a polymer composed of highly branched chains of glucose molecules. The glucose units are linked in 1–4 positions, whereas the branch points are attached in 1–6 linkages. Glycogen molecules are relatively large spherical structures, and their aggregations

are easily recognizable by electron microscopy in cell cytoplasm. Liver has the highest glycogen content of all tissues, usually 3–5 g/100 g wet weight. Skeletal muscle normally contains 0.5–1.0 g/100 g. The glycogen content of liver increases following carbohydrate-rich meals and decreases during periods of fasting. During a fast, liver glycogen is degraded to glucose, which is released into the circulation to maintain glucose homeostasis.

Glycogen synthesis appears to begin with autoglucosylation of the glycoprotein primer glycogenin. The process starts with the attachment of one to two glucose units to a tyrosine residue of the glycogenin. Subsequently, a divalent cation-dependent autoglucosylation reaction occurs, resulting in the addition of six to seven glucosyl residues to the glycogenin. This molecule—glycogenin plus eight glucose residues—serves as the glucan primer for the next step. However, in order for the glucan primer to be utilized, it requires the glycogenin to form a complex with a different enzyme, glycogen synthase. Glycogen synthase is stimulated by insulin and acts as the rate-limiting enzyme of gluconeogenesis. When complexed with the glycogenin primer, glycogen synthase elongates the glucan primer using units from UDP-glucose in the presence of  $Mn^{2+}$ . In order for the chain to continue growing, the glycogen synthase must gradually detach while brancher enzyme completes the process by branching the glycogen molecule.

The following two enzymatic reactions are particularly important in glycogen synthesis:

Reaction 1 involves the formation of UDPG and pyrophosphate (PP) from glucose-1-phosphate and uridine triphosphate (UTP) by the enzyme uridine diphosphate glucose pyrophosphorylase. Reaction 2, catalyzed by glycogen synthase, involves the addition of one glucosyl unit to the glycogen molecule taken from uridine diphosphate glucose, leaving uridine diphosphate (UDP). Brancher enzyme adds new branch positions to the chains.

The regulation of glycogenolysis in liver is complex (Figure 93-5). The most clearly defined mechanism involves activation of the enzyme adenyl cyclase by the hormones glucagon and epinephrine. This increases the cyclic adenosine monophosphate (cAMP) level in the cytosol, which activates protein kinase, phosphorylase kinase (PhK) and phosphorylase in rapid sequence by phosphorylation of these enzymes. Phosphorylase acts upon the terminal units of the glycogen chains liberating glucose-1-phosphate. Debrancher enzyme removes branch points and liberates free glucose.

Several other factors have been shown to affect the activity of phosphorylase, in addition to glucagon and epinephrine. Both vasopressin and angiotensin I activate phosphorylase without increasing cAMP. Ionic calcium enhances and potassium ion inhibits phosphorylase activation. Insulin acts at several levels to inhibit

phosphorylase activity. An amylase that is present in hepatocytes removes oligosaccharide chains, 3–5 units long, from glycogen. Lysosomal acid alpha glucosidase (acid maltase) breaks down glycogen and provides an alternate pathway for glycogen catabolism. The starch binding domain containing protein 1/genthiolin 1 (stbd1) is a recently identified transporter protein important in glycogen metabolism due to its role in attaching to glycogen thereby aiding in its anchorage to various cellular locations (101). The rate of glycogen synthesis increases when the concentration of glucose and insulin rise in the blood and the glucagon level falls. Glycogen synthase is the rate-limiting enzyme in glycogen synthesis, and it is very highly regulated. Insulin stimulates the activity of glycogen synthase by decreasing its level of phosphorylation, either involving activation of p13 kinase through activation of insulin receptor, or involving lowering the level of cAMP in liver, thereby decreasing the level of phosphorylase b and releasing the inhibition of the protein phosphatase 1. A fall in blood glucagon concentration also leads to deactivation of phosphorylase and inhibition of glycogenolysis. In addition to glycogenolysis, gluconeogenesis also plays an important role in maintaining blood glucose levels (102). A substantial amount of glucose production comes from gluconeogenesis during fasting conditions.

The disorders of glycogen metabolism, generally named GSDs, result from deficiencies of various enzymes or transport proteins in the pathways of glycogen metabolism (for review, see Reference (102)). GSDs were originally identified numerically: from GSD type Ia (G6Pase deficiency) to GSD type VI (hepatic phosphorylase deficiency). Now, there are more than 12 known forms of glycogenoses. The authors prefer to designate them according to the enzyme deficiency, and have arbitrarily divided GSDs into three groups: those predominantly affecting the liver, those predominantly affecting muscle tissues and those primarily involving the heart. There are

**FIGURE 93-5** Key enzymes involved in the regulation of glycogenolysis.

disorders where several of these organs and others are involved. Diagnostic procedures for GSDs include carbohydrate and glucagon tolerance tests, measurement of tissue glycogen content, enzyme assays, and DNA mutational analysis. Although GSDs are usually recognized in early childhood, some forms have been found in adults.

## 93.8 GSDS PRIMARILY INVOLVING THE LIVER

### 93.8.1 GSD Type Ia (Glucose-6-Phosphatase Deficiency, von Gierke Disease)

**93.8.1.1 Clinical Aspects.** GSD type I has two biochemical subtypes—GSD Ia and GSD Ib—each derived from deficiencies in particular components of the glucose-6-phosphatase (G6Pase) complex. The G6Pase complex is comprised of the catalytic subunit (G6Pase, glucose-6-phosphatase alpha, G6Pase- $\alpha$ ; responsible for GSD Ia) and glucose-6-phosphate translocase (G6PT; responsible for GSD Ib) (103).

GSD type Ia, described in 1929 by von Gierke, was the first abnormality of glycogen metabolism to be recognized (102). The deficient enzyme, G6Pase, is a key protein in both glycogenolysis and gluconeogenesis that aids in the conversion of glucose-6-phosphate to glucose. Clinical manifestations usually appear in the first 6 months of life. The infant comes to medical attention either because of marked hepatomegaly or because of symptoms of hypoglycemia. Brief periods of fasting (3–4 h) cause irritability secondary to hypoglycemia, usually without convulsions, and tachypnea due to acidosis. Perspiration and heat intolerance accompany a high metabolic rate. Epistaxis and bruising are common. Bowel movements tend to be loose. Renomegaly is characteristic, but the spleen and heart are of normal size. The more severely affected infants and children are prone to severe lactic acidosis during minor infections, and, in the past, the mortality rate during childhood was high. Untreated children grow slowly, and their sexual maturation is delayed.

In GSD I, uric acid production and excretion are increased. Consequently, hyperuricemia and gouty arthritis are common. Renal stones and nephrocalcinosis associated with distal renal tubular acidosis are also common. Patients with GSD I have much higher recurrent nephrolithiasis rate than the general population, as well as higher levels of hypocitraturia than other individuals who suffer from stone formation (104). A type of glomerulosclerosis, similar to that seen in diabetes mellitus with hyperfiltration and microalbuminuria at onset of the renal dysfunction, has been recognized. Diffuse interstitial nephritis and renal failure are late complications.

Cholesterol, mainly low-density lipoprotein cholesterol and triglyceride levels are invariably elevated in blood and occasionally result in cutaneous xanthoma.

Hepatic adenoma formation appears to be almost universal by adolescence. Hemorrhagic necrosis of the hepatic adenomas may cause severe acute abdominal pain and anemia. Several patients have died with hepatocellular carcinoma, suggesting that the adenomas are premalignant lesions. Factors that result in the adenoma to carcinoma transformation include genetics and metabolic control. A recent study showed no significant contrast in metabolic balance between GSD Ia patients who developed adenomas and those who did not (105). However, the presence of adenomas did correlate with significantly elevated serum interleukin 8 in GSD Ia patients, consistent with the hypothesis that chronic injury and elevation of hepatic chemokines play a role in adenoma formation (106).

Other complications include osteoporosis with risk for bone fractures, neurologic deficits (apparently from hypoglycemia), seizures, iron refractory anemia, pancreatitis, thyroid abnormalities and pulmonary hypertension. There is considerable variability in the severity of manifestations in GSD I. A small number of individuals are mildly affected and some are discovered as adults with hepatomegaly and gout. Virtually all women have ultrasound findings consistent with polycystic ovaries. However, the other clinical features of polycystic ovary syndrome such as acne and hirsutism are not noted. Type I GSD also does not appear to affect ovulation and fertility: successful pregnancy has been noted in many individuals with GSD I, although symptoms may be exacerbated due to the pregnancy-related increase in renal perfusion and maternal volume (107). In addition, hypoglycemia may also become more difficult to control. Increased vaginal spotting has also been known to occur secondary to the bleeding abnormalities.

**93.8.1.2 Biochemical Aspects.** The enzyme G6Pase is associated with a complex of translocases, or transport proteins (108). The active site of the enzyme faces the lumen of the endoplasmic reticulum in hepatocytes. The enzyme complex appears to consist of the enzyme protein situated in close proximity to three translocases (T1, T2, and T3), which transport glucose-6-phosphate, phosphate and glucose, respectively, across the membrane of the endoplasmic reticulum. The clinical and biochemical features of GSD Ia result from deficiency of the catalytic subunit of the G6Pase enzyme. The absence or defective function of T1 (also called glucose-6-phosphate translocase or G6PT) results in GSD Ib, which is described later. Defects involving the other proteins of the complex are not well characterized, but may appear clinically similar to deficiency of the enzyme itself.

The production of glucose by glycogenolysis and gluconeogenesis is impaired in GSD Ia (Figure 93-6). Normal plasma glucose concentrations cannot be maintained in the postprandial state, and the resultant hypoglycemia inhibits insulin and enhances pancreatic glucagon secretion. The decrease in the insulin to glucagon ratio in blood stimulates glycogen breakdown in the liver, and in

**FIGURE 93-6** Glycogen metabolism and enzyme deficiency (Glu-6-P translocase and phosphatase) in GSD type I.

the absence of G6Pase, lactic and pyruvic acids are produced in excess, instead of glucose.

The biochemical abnormalities in blood are characteristic in GSD type I. Blood obtained after a brief (3–4 h) fast reveals hypoglycemia (10–40 mg/dL) and elevated lactic acid levels (50–100 mg/dL). In this condition, lactate serves as an important substitute fuel for the brain, and symptoms of neuroglycopenia may be minimal or absent despite hypoglycemia. Hyperlipidemia (primarily hypertriglyceridemia and hypercholesterolemia) and hyperuricemia are almost always present. The plasma may be “milky” in appearance as a result of a striking elevation of triglycerides. Uric acid production is stimulated by glucagon secretion, which causes catabolism of hepatic ATP to uric acid. Glucagon administration causes little if any rise in blood glucose but a marked rise in blood lactate and uric acid levels. Intravenous administration of galactose or fructose causes a rise in blood lactate but no or minimal rise in blood glucose. Other types of GSD such as debrancher and phosphorylase deficiencies, although in some ways clinically similar to GSD type I, have normal blood lactate values in the fasting state.

Fructose-1,6-diphosphatase deficiency is similar clinically to GSD type I. Blood lactate levels are elevated during fasting, and glucagon administration causes a rise in blood glucose but not in lactate. Cholesterol and triglycerides levels are usually normal. The diagnosis of type I disease can be suspected on the basis of clinical presentation and abnormal plasma lactate and lipid values. In addition, administration of

glucagon or epinephrine causes little or no rise in blood glucose but increases lactate levels significantly. Before the glucose-6-phosphatase and glucose-6-phosphate translocase genes were cloned, a definitive diagnosis required a liver biopsy to demonstrate the deficiency. Gene-based mutation analysis now provides a noninvasive way of diagnosis for most patients with types Ia and Ib disease (108).

Histologic findings in the liver in GSD type I include distended hepatocytes filled by glycogen and fat. Despite hepatomegaly, liver enzymes are usually normal or near normal.

**93.8.1.3 Treatment.** The main goal of treatment is the maintenance of euglycemia. Meeting this goal suppresses lactic acid production, decreases blood lipid and uric acid levels and markedly enhances growth. Lactic acid production can be suppressed by administering glucose enterally at a rate of ~8–9 mg/kg/min in an infant, and 5–7 mg/kg/min in an older child. Frequent feedings of carbohydrate during the daytime and supplementation of the diet with uncooked cornstarch (approximately 1.75–2.5 g/kg/6 h, day and night) have been very successful in maintaining euglycemia and promoting growth, especially in older children. Feeding of pancreatic enzymes along with cornstarch has been recommended for infants (who may not adequately digest the starch). New starch products that are thought to be longer acting, better tolerated and more palatable are currently in development. In a short-term double-blind cross-over pilot study comparing uncooked, physically-modified cornstarch to traditional cornstarch, longer duration of euglycemia and better short-term metabolic control in the majority of GSD I patients treated with the new starch was noted (109). Larger studies are needed to confirm the efficacy of this new product.

An alternative nighttime regimen is the infusion of a concentrated glucose solution or high-carbohydrate formula overnight through nasogastric tube or by gastrostomy to maintain euglycemia. Dangers associated with overnight tube feeding include hypoglycemia secondary to accidental interruption of the infusion, and aspiration from regurgitation of the infusate. These treatment regimens produce a marked improvement in strength and growth. Allopurinol may be needed to control hyperuricemia. The hyperlipidemia can be reduced with lipid-lowering drugs such as HMG-CoA reductase inhibitors and fibrates. Angiotensin-converting enzyme (ACE) inhibitors, like captopril, seem to be beneficial in treating microalbuminuria, an early indicator of renal dysfunction in GSD I patients. Citrate supplement may be beneficial in preventing or ameliorating nephrocalcinosis and the development of urinary calculi (110).

Liver transplantation can be lifesaving and can eliminate the problems of recurrent adenomas with the risk for malignant transformation and metabolic derangements such as hypoglycemia, lactic acidosis, and hyperlipidemia. Small hepatic adenomas (<2 cm in diameter)

may be treated with percutaneous ethanol injection or transcatheter arterial embolization.

**93.8.1.4 Genetic Aspects.** G6Pase deficiency is inherited as an autosomal recessive disease. The incidence is estimated to be in the order of 1:150,000 births but may be higher in some population groups. The gene for G6Pase is called G6PC1 and has been mapped to chromosome 17q21 (102). DNA isolated from peripheral blood leukocytes is adequate for molecular diagnosis. The mutations p.Arg83Cys and p.Gln347X are common mutations in Caucasians. Chorionic villus biopsy and amniocentesis have been used for prenatal diagnosis (111). The molecular basis for GSD I has been studied in detail and reviewed (108).

## 93.8.2 GSD Type Ib

**93.8.2.1 Clinical Aspects.** GSD type Ib is caused by deficiency of G6PT, the transport protein portion of the G6Pase complex. The diagnosis of GSD Ib is usually made during infancy, but it has been also recognized during adult life. GSD Ia and Ib are similar clinically, except that neutropenia and neutrophil dysfunction are characteristic of Ib. The neutrophil abnormalities result in frequent infections, oral mucosal lesions, gingivitis and chronic inflammatory bowel disease. Severely reduced chemotaxis and phagocytosis, deficient superoxide anion generation, and altered calcium metabolism have been demonstrated in GSD Ib neutrophils.

**93.8.2.2 Biochemical Aspects.** Some individuals with all the clinical and biochemical manifestations of GSD I have normal G6Pase activity when their liver tissue is assayed after freezing; but when the assay is done on fresh tissue, no enzyme activity is detected. This enzyme is thought to be located on the luminal surface of hepatic microsomes. A specific transport protein is required for the passage of G6P into the microsome lumen. As elucidated in the GSD Ia Biochemical Aspects section, GSD Ib is due to lack of this transport protein, T1 or G6PT. When microsomal membranes are disrupted chemically or by freezing, the enzyme is exposed and expressed in the assay procedure. The lack of enzyme activity in unfrozen liver specimens occurs because G6P does not have access to the enzyme under these conditions. The mechanism for the neutropenia and neutrophil dysfunction in patients with GSD Ib is attributed to premature apoptosis (112). This is thought to be due to lack of NADPH resulting in a diminished capacity to (re) generate reduced glutathione (113,114). Cells would thus be rendered more susceptible to oxidative damage and undergo apoptosis. More recently another mechanism, a defect in neutrophil glycosylation, has been identified as a cause for the neutrophil dysfunction in GSD Ib (115).

**93.8.2.3 Treatment.** The bone marrow in patients with GSD Ib contains abundant neutrophils, and the neutropenia can be improved with the administration of granulocyte-colony stimulating factor (G-CSF). Prolonged

treatment with G-CSF results in a marked reduction in the frequency of infection and partial resolution of inflammatory bowel disease. Derivatives of 5-aminosalicylic acid (5-ASA) may be a helpful adjunct for treating the inflammatory bowel disease in GSD Ib patients; renal function needs to be monitored (112). In case, if patients do not respond well to G-CSF or 5-ASA therapies for the gastrointestinal manifestations, adalimumab may be an effective therapeutic option (116). Liver transplantation may be beneficial for indications as it is in GSD Ia (117). Neutropenia, however, typically persists in type Ib patients after liver transplantation, necessitating continuous treatment with G-CSF in some instances.

**93.8.2.4 Genetic Aspects.** The inheritance pattern is autosomal recessive. The gene for GSD Ib, SLC37A4 encoding G6PT, has been mapped to 11q23.3 (118). Two mutations, c.1042delCT and p.Gly339Cys, are prevalent in Caucasian patients, whereas p.Trp118Arg appears to be most common in Japanese patients. At this time, over 85 mutations have been identified, including a novel missense mutation described in a case report that appears to be associated with early-onset neutropenia (119,120). Carrier detection and prenatal diagnosis are possible with the use of molecular techniques.

Successful pregnancies with careful management of varying mild complications have been noted in patients with GSD Ib (121).

## 93.8.3 GSD Type Ic

Several patients with clinical features similar to those of GSD Ib, including neutropenia, have been reported to have a defect in the microsomal transport of phosphate and pyrophosphate (labeled T2). This defect, once characterized as a separate disease by the name of GSD Ic, is now known to be allelic to GSD Ib, alluding to the discovery that the G6PT gene functions as both a G6P and a phosphate transporter (102,122). This binary function explains how several patients with GSD Ic have had mutations in the G6PT reported (102).

## 93.8.4 GSD Type III (Amylo-1,6-Glucosidase (Debrancher) Deficiency, Limit Dextrinosis, Cori Disease, Forbes Disease)

**93.8.4.1 Clinical Aspects.** GSD type III (GSD III) is caused by a deficiency of glycogen debrancher enzyme (GBE), a single polypeptide that has both amylo-1,6-glucosidase (EC 3.2.1.33) and 4- $\alpha$ -glucanotransferase (EC 2.4.1.25) activities (123). GDE has three main domains, which include the transferase domain, glucosidase domain, and a carbohydrate-binding domain (CBD). Mutations in each domain affect the corresponding function of the overall enzyme, however, mutations in the CBD tend to prove the most severe (123). Inherited deficiencies of debrancher enzyme have been reported to involve both liver and muscle (cardiac

and skeletal) (GSD IIIa) and liver only (GSD IIIb). It is estimated that 75–85% of those with GSD III have type IIIa, approximately 15–25% have type IIIb. Debranching enzyme and phosphorylase are responsible for complete degradation of glycogen. When debranching enzyme is defective, glycogen breakdown is incomplete, and an abnormal glycogen accumulates that has short outer chains and resembles limit dextrin.

The clinical manifestations of GSD III can be recognized in infancy. Abdominal distention due to hepatomegaly is moderate to marked; splenomegaly is minimal or moderate. Hypoglycemia is present and often accompanied by ketonuria, especially after overnight fasting. Unlike in GSD I, there is no bleeding tendency, heat intolerance, loose stools, rapid breathing, or enlargement of the kidneys in GSD III.

These children usually survive childhood without difficulty, although growth may be slow. Hepatomegaly decreases with maturity, adenoma formation is infrequent, but cirrhosis, portal hypertension, hepatocellular carcinoma, and liver failure may occur.

In patients with muscle involvement (type IIIa), muscle weakness is usually minimal during childhood but can become severe during the third or fourth decade of life, as evidenced by slowly progressive weakness and muscle wasting (124). Electromyographic changes are consistent with a widespread myopathy, and nerve conduction may be abnormal (125). Ventricular hypertrophy is frequent, but overt cardiac dysfunction is rare. A recent case study of a GSD III patient presenting with premature coronary artery disease showed that patients with GSD III may have a higher susceptibility to cardiac complications and therefore may need to be screened and subjected to preventative measures (126). There are also reports of sudden cardiac death, likely due to cardiac arrhythmias. Myocardial fibrosis has also been reported in a 32-year-old patient with GSD III using cine cardiovascular magnetic resonance (127). In some patients, hepatic symptoms may be so mild that the diagnosis is not made until adulthood, when neuromuscular disease becomes manifest. Multi-parametric functional NMR imaging and spectroscopy have been used as noninvasive methods for quantification of muscle-wasting myopathy in GSD III (128). Some individuals with GSD III may be at an increased risk of osteoporosis (129). The etiology is unclear but likely related to the underlying myopathy. Polycystic ovary appears to be a common finding in female patients; fertility, however, does not seem to be reduced (130). There have been reports of successful pregnancy outcome in GSD III (131).

**93.8.4.2 Biochemical Aspects.** Defects in either enzymatic subunit—4- $\alpha$ -glucanotransferase or amylo-1,6-glucosidase—of debrancher enzyme result in glycogen accumulation in liver and many other tissues, including leukocytes and erythrocytes. In the fasting state, blood glucose levels are sustained primarily by gluconeogenesis

and by limited glycogen degradation. A moderate elevation of serum transaminase activity is common in GSD III. Hyperlipidemia may be present but hyperuricemia is usually absent (132). Blood lactate levels are normal in the fasting state, and there is no significant rise in blood glucose or lactate values following glucagon administration. Creatine phosphokinase activity in blood is high in GSD IIIa and reflects debrancher enzyme deficiency in muscle. However, if this appears normal it does not exclude a diagnosis of GSD IIIa. The histology of the liver is characterized by a universal distention of hepatocytes by glycogen and by the presence of fibrous septa. The fibrosis and the paucity of fat distinguish type III from type I glycogenosis. The fibrosis can range from minimal periportal fibrosis to micronodular cirrhosis.

Debrancher deficiency can be confirmed by demonstrating the absence of enzyme activity in liver and muscle in GSD IIIa and only in liver in GSD IIIb. Cultured fibroblasts may be used to confirm this deficiency. Erythrocytes and leukocytes have also been used for diagnosis (133).

**93.8.4.3 Treatment.** Therapy is directed toward preventing hypoglycemia and reducing the breakdown of muscle protein for gluconeogenesis by frequent feeding, a high-protein diet and the avoidance of prolonged periods of fasting. Treatment regimens that are employed for type I GSD have been used for type III. Cornstarch therapy reduces the demand for gluconeogenesis. Limitation of fructose and galactose intake is not necessary as in the case of GSD I although restriction of dietary fat seems prudent. A high-protein diet with particular attention to overnight carbohydrate and protein administration can markedly improve growth and has been advocated to treat or prevent myopathy. Successful liver transplantation for hepatic failure has been reported.

**93.8.4.4 Genetic Aspects.** The type III glycogenoses are inherited as autosomal recessive traits. The gene for debranching enzyme, amylo-1,6-glucosidase, is located on chromosome 1p21. At least 50 different mutations that cause type III disease have been identified (123,134). Two mutations (c.18\_19delGA (p.Gln6HisfsX20) and c.16C>T (p.Gln6X)), both located in exon 3 at amino acid codon 6, are exclusively found in the subtype IIIb (132,135). Various mutations have been recognized in specific populations: c.2309-1 G>A (11.8% of non-Hispanic Caucasians), c.1384delG (about half of the Hispanic alleles), and several founder mutations in patients from north Africa (Sephardic Jews), the Faroe Islands, Italy, the Mediterranean region, and Turkey (123). A study of 15 Irish patients with GSD III from eight different families recently revealed a variety of novel mutations including p.Thr512fs, p.Ser736fs, p.Ala1400fs, p.Lys1407fs, p.Tyr519X and p.Asp627Tyr, in addition to highlighting how the severity of the symptoms reflects the allelic composition (136). Carrier detection and

prenatal diagnosis are possible with DNA-based linkage or mutation analysis.

### 93.8.5 Brancher Deficiency (GSD Type IV, Amylopectinosis, Amylo-1,4-1,6-Transglucosidase Deficiency, Anderson's Disease)

**93.8.5.1 Clinical Aspects.** Brancher deficiency is rare. Affected infants begin to show evidence of liver dysfunction within the first year of life, and death by 2–4 years appears to be the usual outcome. Features of hepatic failure and portal hypertension appear including growth failure, jaundice, hepatosplenomegaly, and prominent abdominal venous pattern. Hypotonia is common, but hypoglycemia is not a feature. Incidences of nonprogressive liver involvement have also been reported.

A neuromuscular form of type IV GSD has also been reported. Patients with this disease may present (1) at birth with fetal akinesia deformation sequence, fetal hydrops, arthrogryposis, and eventual death due to cardiac or respiratory complications (137), (2) at birth with severe hypotonia, muscle atrophy, and neuronal involvement and during the neonatal period with death (138), (3) in late childhood with myopathy or cardiomyopathy (139,140), or (4) as adults with diffuse central and peripheral nervous system dysfunction accompanied by accumulation of polyglucosan bodies in the nervous system (so-called adult polyglucosan body disease) (141).

**93.8.5.2 Biochemical Aspects.** An abnormal form of glycogen, with long-chain and infrequent branch points, accumulates in many cell types, including hepatocytes, skeletal and myocardial muscle cells, fibroblasts, leukocytes, and nerve cells. Hepatic cirrhosis is presumed to result from the collection of the abnormal type of glycogen. Carbohydrate and glucagon tolerance tests are normal, provided that liver failure is not severe at the time of testing.

Deficiency of brancher enzyme can be demonstrated by enzyme assay in liver tissue, in leukocytes, and in cultured fibroblasts. The histologic findings in the liver are characterized by both micronodular cirrhosis and faintly stained basophilic inclusions in the hepatocytes. The inclusions consist of coarsely clumped, stored material that is periodic acid-Schiff-positive and partially resistant to diastase digestion. Electron microscopy shows, in addition to the conventional glycogen particles, an accumulation of fibrillar aggregations typical of amylopectin. This disease must be differentiated from other forms of liver failure in infancy, such as neonatal viral hepatitis, biliary atresia, polycystic disease of liver and kidney, Wilson's disease, and 1-antitrypsin deficiency. Heterozygotes appear to be detectable by enzyme assay of cultured skin fibroblasts.

**93.8.5.3 Treatment.** There is no specific treatment for type IV GSD. For progressive hepatic failure, liver

transplantation has been performed. However, caution should be taken in selecting patients for liver transplantation because a nonprogressive hepatic form of the disease exists, and extrahepatic manifestations of the disease may manifest after transplantation in other forms.

**93.8.5.4 Genetic Aspects.** This disorder is inherited as an autosomal recessive trait. The enzyme is normally present in cultured amniotic fluid cells, and prenatal diagnosis has been accomplished (142). The glycogen branching enzyme (GBE) gene is located on chromosome 3p12, according to OMIM. Both hepatic and neuromuscular forms are caused by mutations in the same GBE gene, *GBE1* (102). There have been over 34 mutations and 17 polymorphisms found in the *GBE1* gene. The large number of mutations explains the phenotypic variety. Two missense mutations typically cause a milder form of GSD IV, while large deletions and protein-truncating mutations typically cause the severe congenital form (137). A number of the mutations occur in or near exon 12, suggesting that this region is a mutation “hotspot” for the disease (143).

### 93.8.6 GSD Type VI (Hepatic Phosphorylase Deficiency, Hers Disease)

**93.8.6.1 Clinical Aspects.** Hepatic phosphorylase deficiency was first identified by Henri-Géry Hers in 1959 when he saw three patients presenting with hepatomegaly and glycogen storage in the liver. Although the activities of the G6Pase catalytic subunit and debranching enzyme appeared normal, the activity of liver phosphorylase remained highly restricted (144). In 1960, Stetten and Stetten labeled this deficiency of hepatic phosphorylase “Hers Disease,” or GSD type VI (145).

In early childhood, patients with GSD VI usually present with hepatomegaly and growth retardation. The clinical course can vary from mild to severe; laboratory findings include hypoglycemia, hyperlipidemia, and hyperketosis. Lactic acid and uric acid appear normal. There is no involvement of the heart or skeletal muscles. Around puberty, the hepatomegaly begins to improve with age and usually disappears. Clinical heterogeneity exists; Beauchamp et al reported a variety of cases with a more severe clinical course including significant hepatomegaly, recurrent severe hypoglycemia and postprandial lactic acidosis (146). A case of a GSD VI female presenting with a hepatic tumor, which is usually only seen in patients with GSD Ia and III, suggests that screening for adenomas should be done for patients with GSD VI (147). Hepatocellular carcinoma was reported upon histological examination of the explanted liver of a GSD VI female who underwent liver transplantation due to rapidly growing hepatocellular adenomas (148).

**93.8.6.2 Biochemical Aspects.** Phosphorylase exists in three isoforms: the muscle (M), the liver (L), and the brain (B). Each isoform is encoded by genes designated as *PYGM*, *PYGL*, or *PYGB*, which are located on

chromosome 11, 14 and 20, respectively. Mutations of the *PYGM* gene are associated with GSD V (McArdle's Disease), a condition caused by muscle phosphorylase deficiency (see later). Mutations in the *PYGL* gene, on the contrary, elicit GSD VI (Hers Disease) or liver phosphorylase deficiency. Thus far, the *PYGB* gene has not been tied to any form of GSD.

Deficiency of phosphorylase (or one of the enzymes that leads to its activation) obstructs glycogen degradation in the liver. The absence of severe fasting hypoglycemia may be explained by the fact that phosphorylase activity is usually only partially deficient and that hepatic gluconeogenesis is intact. However, there are cases with severe fasting hypoglycemia. Laboratory studies reveal mild to moderate elevations of serum transaminase values, ketonemia and hyperlipidemia. Fasting blood lactic and uric acid levels are normal. Blood lactate values may triple following meals and after glucose, galactose, and fructose loading. Glucagon administration is reported to cause minimal glycemic response in patients with phosphorylase deficiency.

**93.8.6.3 Treatment.** Presentation of symptoms determines treatment protocol. Although most patients do not require a specific treatment, a high-carbohydrate diet and frequent feeding are effective in preventing hypoglycemia.

**93.8.6.4 Genetic Aspects.** The liver phosphorylase gene (*PYGL*) is on chromosome 14q21–22 and has 20 exons. Many mutations are known in this gene; several are missense mutations. One missense mutation of the *PYGL* gene, p.Gly233Asp, was identified in a Chinese patient, and a splice-site mutation in intron 13 was determined in the Mennonite population (149).

## 93.8.7 GSD Type IX (Phosphorylase Kinase Deficiency)

**93.8.7.1 Clinical Aspects.** Physical features of liver phosphorylase kinase (PhK) deficiency are usually recognizable within the first 2 years of life and include short stature and abdominal distention from moderate to marked hepatomegaly (102). The clinical severity of liver PhK deficiency varies considerably. Hyperketotic hypoglycemia, if present, is usually mild but can be severe in some cases. Ketosis may occur even when glucose levels are normal. In some children, there may be mild delays in gross motor development and hypotonia. Liver fibrosis can occur and progress to cirrhosis in rare cases, particularly in patients with *PHKG2* mutations (150). Liver adenoma appears to be very rare. Cognitive and speech delays have been reported in a few individuals, but it is not clear whether these delays are caused by PhK deficiency or whether they are coincidental (151,152). Polycystic ovaries are common in females with liver PhK deficiency (130). Renal tubular acidosis has been reported in a few cases (151,152). Cardiac manifestations have not been reported in liver PhK deficiency. Unlike in GSD I, lactic

acidosis, bleeding tendency, and loose bowel movements are not characteristic, although may be present. Although growth is retarded during childhood, normal height and complete sexual development are eventually achieved (153,154). As with debrancher deficiency, abdominal distention and hepatomegaly usually decrease with age and may disappear by adolescence. Most adults with liver PhK deficiency are asymptomatic, although further long-term studies are needed to fully assess the impact of this disorder in adults (154,155).

**93.8.7.2 Biochemical Aspects.** PhK is composed of four copies each of the four following subunits:  $\alpha$ ,  $\beta$ ,  $\gamma$  and  $\delta$ . The  $\gamma$  subunit provides the catalytic activity, which is regulated by phosphorylation of the  $\alpha$  and  $\beta$  subunits. The  $\delta$  subunit is calmodulin. Several isoforms of each have been identified. The  $\alpha$  subunit is encoded by the *PHKA1* gene in muscle and the *PHKA2* gene in liver; the  $\beta$  subunit is encoded by the *PHKB* gene and is alternatively spliced in liver and muscle; the  $\gamma$  subunit is encoded by *PHKG1* in muscle and *PHKG2* in liver, and the  $\delta$  subunit (calmodulin) is encoded by the *CALM1*, *CALM2*, and *CALM3* genes in both (152,156). PhK activity is reduced in the liver, erythrocytes, and leukocytes of most individuals with liver PhK deficiency. X-linked liver PhK deficiency, caused by mutations in the *PHKA2* gene, is subdivided into two biochemical subtypes: XLG1, with measurable deficiency of PhK activity in blood cells and liver in vitro, and XLG2 with normal PhK activity in blood cells and variable activity in liver in vitro, but presumably deficient in vivo. While not fully understood, it has been suggested that mutations affecting the regulation of the enzyme, such as missense mutations, result in XLG2, while mutations affecting the amount of protein, such as nonsense mutations, are more likely to result in XLG1 (157). Mutations causing these two subtypes also cluster in different functional domains of the protein (158).

Liver tissue histology shows steatosis, glycogenosis, and may show mild periportal fibrosis, and cirrhosis in rare cases. At diagnosis, individuals with liver PhK deficiency usually have elevated liver transaminases, mildly elevated triglycerides and cholesterol, normal uric acid and lactic acid concentrations, and normal glucagon response (142,156).

**93.8.7.3 Treatment.** In individuals with liver PhK deficiency, hypoglycemia can be prevented by frequent daytime meals that are high in complex carbohydrates and protein. In patients with normal renal function, protein can comprise 15–25% of total calories consumed. Cornstarch can be given with symptom-dependent dosage and timing (0.6–2.5 g/kg every 6 h). Hypoglycemia, if present, should be treated with oral intake. If not tolerated, intravenous glucose should be administered (156).

Growth may be improved by carbohydrate supplementation, presumably by reducing the demand for gluconeogenesis and increasing insulin secretion. Because of

liver enlargement, activities that might lead to abdominal trauma should be approached with caution.

**93.8.7.4 Genetic Aspects.** Liver PhK deficiency can be caused by mutations in the *PHKA2*, *PHKG2*, and *PHKB* genes. Mutations in *PHKA2*, which maps to Xp22.2–Xp22.1, cause X-linked liver PhK deficiency, also known as X-linked glycogenosis. As the most common form of PhK deficiency and one of the most common liver glycogenoses, it accounts for about 75% of PhK cases. The severity of clinical symptoms associated with X-linked liver PhK deficiency is highly variable and can range from mild to severe (152). Typically, female carriers of *PHKA2* mutations are asymptomatic but, depending on the pattern of X-inactivation, some may have symptoms. *PHKG2*, located on 16p12.1–p11.2 causes an autosomal recessive form of liver PhK deficiency that tends to be more severe, progressing to liver cirrhosis in some cases (151). Autosomal recessive liver PhK deficiency is also caused by mutations in the *PHKB* gene on chromosome 16q12–q13. Patients with mutations in this gene typically have a mild clinical course. Although *PHKB* mutations result in PhK deficiency in muscle as well as liver, symptoms of muscle involvement are mild or absent (152,159). The incidence of these disorders is estimated to be approximately 1:100,000.

## 93.9 OTHER LIVER GLYCOGENOSES

### 93.9.1 GSD Type 0 (Liver Glycogen Synthase Deficiency)

Although liver glycogen synthase deficiency (GSD 0) does not involve glycogen storage, it is often included in discussions of GSD. Case reports are few, but the clinical picture is of symptomatic hypoglycemia and ketosis in the fasting state, usually without hepatomegaly (160). Patients present in early infancy with early morning drowsiness and fatigue and sometimes with convulsions associated with hypoglycemia and hyperketonemia. Fasting hypoglycemia is accompanied by low plasma lactate and alanine levels and elevated plasma ketones. These changes are promptly relieved with carbohydrate intake, and postprandial hypoglycemia is common. The hypoglycemia may be very mild or severe enough to cause convulsions. A marked rise in blood lactate follows loading with glucose or galactose. A minimal rise in blood glucose is expected following glucagon administration in the fasting state. Rare patients presenting with hyperglycemia and glucosuria have also been reported (161).

Glycogen is present in hepatocytes but usually in low to normal concentrations. The glycogen content in muscle is normal. In affected individuals, glycogen synthase is absent from liver but present in muscle. Although hypoglycemia during fasting can continue to be a problem, the long-term prognosis is relatively good. Common features of liver glycogen synthase deficiency include short stature and osteopenia.

GSD 0 can be treated effectively with frequent high-protein feeds, starting in the early morning hours and continuing during the daytime, and supplemental feeds of uncooked cornstarch at bedtime to prevent nocturnal hypoglycemia and ketosis. Several isozymes of glycogen synthetase are known. There is a 70% homology of cDNA sequence encoding the liver and muscle enzymes. The gene for muscle glycogen synthase (*GYS1*) has been localized to 19q13.3. The gene for liver glycogen synthase (*GYS2*) was found at 12p12.2. Several mutations of this gene have been identified in patients with GSD 0. GSD 0 is transmitted as an autosomal recessive condition.

### 93.9.2 GSD Type XI (Fanconi–Bickel Syndrome)

**93.9.2.1 Clinical Aspects.** This rare syndrome is recognized on the basis of rickets, hepatomegaly, and growth failure associated with impaired glucose and galactose tolerance, increased renal clearance of glucose, amino acid, protein, phosphate, and uric acid. In the first year of life, the affected child presents with failure to thrive, rickets, and a protuberant abdomen due to hepato- and renomegaly (162). Developmental delay during puberty is most often acute and it is common to see short stature or dwarfism in adult patients. In addition to storing excess fat in the abdomen and shoulders, patients with GSD XI often present with a “moon-shaped” face (163). Those with this deficiency may encounter fractures as a result of early-onset, generalized osteopenia. Late-onset hypophosphatemic rickets and osteoporosis are common characteristics. Furthermore, intestinal malabsorption and diarrhea may occur. One case revealed abnormal neonatal screening for galactosemia with elevated blood galactose accompanied with retarded growth, moderate hepatomegaly, and delayed bone age, with the first radiologic signs of rickets (164).

**93.9.2.2 Biochemical Aspects.** The disease may be confused with type I GSD, as a Fanconi-like syndrome can develop in type I patients (165). The pathogenesis of this disorder was unknown until 1997 when mutations in the facilitative glucose transporter 2 (*GLUT2*) were identified (see section on glucose transport defects) (166). *GLUT2* is responsible for shuttling glucose in and out of hepatocytes, pancreatic  $\beta$  cells and the basolateral membranes of intestinal and renal epithelial cells (167,168). Affected patients have either low or normal fasting plasma glucose levels and normal fasting lactate values. After oral galactose administration, there is an excessive rise in blood lactate. The glycemic response to glucagon is variable. Histologic findings show increased glycogen content in liver.

**93.9.2.3 Treatment.** Symptomatic treatment with phosphate and bicarbonate resulted in marked growth improvement. Rickets improves with oral phosphate and vitamin therapy in pharmacologic doses (169).

**93.9.2.4 Genetic Aspects.** The gene responsible for GSD XI is the *SLC2A2* (or *GLUT2*) gene, however,

one case without SLC2A2 involvement suggests that either there may be another mutation present in the promotor or intronic region of the *SLC2A2* gene or there are other gene mutations to consider (170). One patient was found to have a 3-bp deletion of the *GLUT2* gene (164). A 4-year-old girl in India presenting with Fanconi-Bickel syndrome revealed a homozygous deletion insertion (162). Pregnancy has been reported in two women with the *GLUT2* defect, while one suffered only a few minor pregnancy complications like gestational diabetes and the other underwent daily hemodialysis, each successfully carried and delivered healthy babies (171,172).

### 93.9.3 Glucose Phosphate Isomerase (Phosphoglucose isomerase, Glucose-6-Phosphate Isomerase) Deficiency

The features of this disorder include severe nonspherocytic hemolytic anemia, hepatomegaly and muscle weakness. Liver and erythrocytes contain excessive amounts of glycogen. Glucose phosphate isomerase activity is decreased in many tissues, including erythrocytes and leukocytes. Two patients with GPI deficiency had additional features, including mental retardation, muscle weakness, and/or hepatomegaly. They had excessive amounts of glycogen in the muscle, liver, and erythrocytes. There was no hypoglycemia. Frequent meals with a diet low in carbohydrate normalized the liver size in one patient (173,174).

## 93.10 GSD PRIMARILY INVOLVING MUSCLE

### 93.10.1 GSD Type II (Lysosomal Acid $\alpha$ -Glucosidase Deficiency, Pompe Disease, Acid Maltase Deficiency, $\alpha$ -1,4-Glucosidase Deficiency)

**93.10.1.1 Clinical Aspects.** Acid  $\alpha$ -glucosidase (GAA) deficiency was first recognized in infants with hypotonia and cardiomegaly without murmur. Subsequently, a range of phenotypes—each including myopathy but differing in age at onset, organ involvement, and clinical severity—has been identified. In the infantile form, glycogen accumulates in almost all tissues. The involvement of cardiac, skeletal, and smooth muscle, and neural cells is the most significant for the affected infant. Manifestations usually appear within the first 6 months of life and include hypotonia and developmental delay, macroglossia, moderate hepatomegaly, marked cardiomegaly, and congestive heart failure. Skeletal muscle may be unusually firm to palpation, with a marked hypertrophy of calf muscles. Affected infants have a “floppy baby appearance.” Infantile Pompe, a generally rapidly progressive condition, leads to death by 1–2 years of age.

Characteristic electrocardiograph abnormalities include shortened PR interval, increased QT dispersion, and large left ventricular voltages. Histologic examination reveals glycogen accumulation in virtually every cell type. The excess glycogen is found within membrane-bound structures (lysosomes) as well as free in the cytoplasm.

Juvenile and adult-onset (late-onset) Pompe disease may manifest by gradually increasing muscle weakness during childhood or as late as the seventh decade of life. Transaminase and creatine kinase levels in serum may be elevated. Skeletal muscle weakness, decreased exercise tolerance, and decreased respiratory reserve are the usual features. These patients often present with a proximal limb girdle muscle weakness. The muscles most susceptible to weakness are those of the pelvic girdle, paraspinal region, and diaphragm (175,176). Hepatomegaly, macroglossia, and cardiomegaly are typically absent in this form. With disease progression, patients become confined to wheelchairs and require artificial ventilation. Respiratory insufficiency is the primary presentation in some patients and many succumb to its complications. The age of death varies from early childhood to late adulthood, depending on the rate of disease progression and the extent of respiratory muscle involvement (177). Basilar artery aneurysms with rupture are another cause for mortality. Other features of the disease include ptosis, lingual weakness and dilatation of the ascending aorta (178).

**93.10.1.2 Biochemical Aspects.**  $\alpha$ -1,4- and  $\alpha$ -1,6-glucosidase activities are associated with a single lysosomal enzyme protein. These activities promote hydrolysis of glycogen to glucose, and absence of these enzymes results in glycogen accumulation within lysosomes.

In the infantile form acid  $\alpha$ -1,4-glucosidase is significantly reduced or absent in affected tissues (e.g. skin, muscle, liver and cultured fibroblasts). In general, higher residual activity is found in patients with the juvenile and adult forms of Pompe disease. Blood-based assays (dried blood spots, leukocytes, or blood mononuclear cells) can also be used for the determination of the enzyme activity. The results of enzyme assay in these blood-based assays can only be interpreted reliably with addition of acarbose in the assay to eliminate nonspecific glucosidase activity (179). Blood-based assays have the advantage of a rapid turn-around time. Skin fibroblast assay is usually preferred to muscle biopsy because it is a less invasive procedure. Muscle biopsy can yield faster results and provide additional information especially in cases where the evaluation is for a limb girdle muscle dystrophy. A major limitation of a muscle biopsy in late-onset patients is the variable pathology: as glycogen accumulation varies in different muscles and within muscle fibers, muscle histology and glycogen content can vary depending on the site of muscle biopsy. In the case of infants, it should be noted that muscle biopsy carries

a very high anesthesia risk. Glucose tetrasaccharide has been shown to be elevated in urine and plasma of the affected patients, particularly the infantile form (180). It is a valuable noninvasive biomarker in diagnosis and monitoring response to therapy in Pompe disease.

**93.10.1.3 Treatment.** Enzyme replacement therapy via a bimonthly 20 mg/kg body weight intravenous infusion of alglucosidase alfa, a recombinant acid  $\alpha$ -glucosidase, is available as a definitive treatment for Pompe disease (181,182). In clinical trials, alglucosidase alfa has been shown to improve ventilator-free survival, cardiomyopathy and growth in patients with infantile-onset Pompe disease as compared to an untreated cohort (183). Stabilization of pulmonary disease and improvement in skeletal muscle function has been noted in patients with late-onset Pompe disease: a randomized study with alglucosidase alfa treatment significantly improved patients' walking test abilities and stabilized pulmonary function (184,185). Early treatment is necessary for maximum efficacy: delays in treatment have resulted in more dismal outcomes (186–189). Newborn screening has resulted in early identification of cases in Taiwan as well as significant outcome improvement due to early start ERT in comparison with babies clinically diagnosed at a later age (190).

A high-protein diet may be useful in Pompe disease. Nocturnal ventilatory support in late-onset patients improves the quality of life and is beneficial during a period of respiratory decompensation. Across the disease spectrum, early diagnosis is crucial in allowing for timely intervention. The availability of the lower-risk blood-based assays is a step toward achieving this goal.

**93.10.1.4 Genetic Aspects.** The infantile and late-onset forms are inherited as autosomal recessive disorders. In one Dutch study, infantile, juvenile, and adult-onset Pompe disease population ratios were 1:101,000, 1:720,000, and 1:53,000, respectively (note wide confidence intervals) (191). Infantile-onset disease is thought to have a high frequency of 1:14,000 in African-Americans, whereas adult-onset has the high frequency of around 1:60,000 in Caucasian populations (192,193). In Taiwan, it is estimated that 1:50,000 children have GSD II (194). The successful newborn screening program in Taiwan, which was first piloted in 2005, detected that 1:34,348 (6:206,088) newborns have early-onset Pompe disease and 1:26,466 have late-onset (190,195). Asian populations have a high percentage (3.3–3.9%) of alpha glucosidase pseudodeficiency, complicating newborn screening and requiring removal of hemoglobin through precipitation (196). The c.[1726A; 2065A] pseudodeficiency allele is responsible for low GAA activity occurrence in typical homozygous individuals and can cause a newborn screening test to appear falsely positive (197).

The gene for GAA has been assigned to chromosome 17q25. More than 289 mutations have been identified, and genotype–phenotype correlation may help to predict the clinical course (198,199). A splice-site mutation

(IVS1-13T>G) is seen in up to 60% of patients with adult-onset Pompe disease. P.Gly828\_Asn882del and p.Glu176ArgfsX45 mutations are both relatively prevalent in the Dutch population and are linked to the infantile form (200). Infantile Pompe disease in the Chinese population of Taiwan is greatly attributed to the p.Asp645Glu mutation (201). P.Arg854Ter is responsible for infantile onset in African-Americans (192). Prenatal diagnosis is possible using cultured amniotic fluid cells or chorionic villus biopsy by measuring the enzyme activity or by mutation analysis.

## 93.10.2 GSD Type V (Muscle Phosphorylase Deficiency, McArdle Disease Myophosphorylase Deficiency)

**93.10.2.1 Clinical Aspects.** Glycogen muscle phosphorylase (MP) deficiency usually becomes manifest in late adolescence or in the second decade of life. However, there are several studies showing that the disease can manifest later on, even as old as 74 years of age (202,203). Other studies reveal an early-onset, fatal form of McArdle disease, which was characterized by hypotonia, overall muscle weakness, and intensifying respiratory complications (204–207). The major symptoms are pain and stiffness of muscles during exercise, which may be due to excessive skeletal muscle recruitment (208). Strenuous activity can result in myoglobinuria. Several instances of acute renal failure due to rhabdomyolysis have been reported. Muscle groups that are stressed may acutely become swollen and tender. In later life, muscle weakness may become chronic. Asymptomatic individuals with absent MP activity have been recognized because of elevated levels of creatine kinase in serum (209).

Due to provocation of symptoms, patients with McArdle disease are advised against short, intense bursts of energy expenditure (sustaining heavy loads) as well as mild yet prolonged expenditure (walking up steep inclines). Contrastingly, everyday activities that require moderate expenditure such as walking on even pavement pose little obstacles for patients as long as they carry along at a pace comfortable for them. A phenomenon known as the “second wind” is commonly reported in patients with McArdle: if a patient momentarily halts the strenuous task at first onset of muscular pain, he or she can continue the activity with greater ease shortly thereafter. The explanation for this anomaly is attributed to increased oxidative capacity, which can be enhanced by the glucose infusion during exercise (210). GSD V, a suspected cause of statin-induced myopathy, intimates the necessity for further evaluation of patients with this presentation (211).

It has been recently suggested that there may be a link between GSD V and cognitive impairment (212).

**93.10.2.2 Biochemical Aspects.** The clinical manifestations result from deficient energy production in

muscle. During muscle activity, glycogen is normally broken down, providing energy for muscle contraction. Glycogen degradation is blocked in MP deficiency, and the defect in glycolysis is reflected in the absence of lactate production by muscle during ischemic exercise. Studies using  $^{31}\text{P}$  nuclear magnetic resonance show a rapid exhaustion of phosphocreatinine during ischemic exercise and indicate the importance of normal glycogen metabolism in muscle activity. A marked deficiency of NADH generation during exercise has also been demonstrated. Ammonia, inosine, hypoxanthine, and uric acid levels in blood increase after muscular activity, apparently due to accelerated degradation of muscle purine nucleotides, ATP, ADP, and AMP. These changes are also seen in GSD types III and VII.

Muscle biopsy for measurement of glycogen content, enzyme, and mutation analysis have been the standards for diagnosis of GSD type V. Muscle histology in GSD V shows damaged fibers, increased glycogen content, and absence of MP histochemical activity. MP activity may be present in regenerating fibers owing to the presence of a fetal-type isozyme. This isozyme has been demonstrated in cultured muscle cells from affected individuals. Phosphorylase activity in liver is normal in GSD type V.

**93.10.2.3 Treatment.** In general, avoidance of strenuous exercise can prevent major episodes of rhabdomyolysis, however, regular and moderate exercise is recommended to improve exercise capacity. Sucrose or glucose given before exercise can markedly improve tolerance in these patients (213). A high-protein diet may increase muscle endurance, and creatine supplementation has been shown to improve muscle function in some patients (214). However, a recent study showed that high-dose creatine supplementation could in fact increase muscle pain, thereby impairing activities of daily living (215). Free fatty acids provide an essential yet limited amount of muscle fuel, therefore therapies that increase the maximum rate of free fatty acid oxidation and consequently boost muscle performance are needed (216). In general, avoidance of strenuous exercise prevents the symptoms. Longevity does not appear to be affected.

**93.10.2.4 Genetic Aspects.** GSD V is inherited as an autosomal recessive trait. The gene for myophosphorylase, PYGM, is located on chromosome 11q13. A number of mutations in the PYGM gene have been uncovered (217). It should be noted that in more recent publications, the new numbering system, based on the first methionine as codon 1, has been used (218). The most common mutation in patients in the United States is a nonsense mutation that changes an arginine to a stop codon (p.Arg50X) (217), and the most common mutation in the Japanese is deletion of a single codon (p.Phe710del). In a population of British Caucasian patients with GSD V, 96% had at least one of two mutated alleles: pArg50X and pGly205Ser (219). These features allow DNA-based diagnosis and carrier detection in these three populations. In patients with

myophosphorylase deficiency, Martinuzzi and coworkers found an association between increased clinical severity and the D allele of the ACE insertion/deletion (I/D) polymorphism (220). This may explain some of the phenotypic variability of the disorder.

### 93.10.3 GSD Type VII (Muscle Phosphofructokinase Deficiency, Tarui Disease)

**93.10.3.1 Clinical Aspects.** Phosphofructokinase (PFK) deficiency is associated with several different clinical pictures. Most commonly, the clinical features are very similar to those of McArdle disease. In the classical form of PFK deficiency, exercise tolerance is limited by skeletal muscle cramps and pain. Symptoms usually begin during childhood, but the diagnosis is often made during adolescence or later. Strenuous exercise causes muscle pain, malaise, nausea, and myoglobinuria. Other clinical variants that have been reported include: (1) infantile hypotonia, limb weakness and a rapidly progressive myopathy leading to early death (age 4 years) (221–224), (2) infantile congenital myopathy and arthrogryposis with early mortality, (3) infantile presentation of hypotonia, mild developmental delay, and seizures, (225,226) adulthood presentation of a slowly progressive, fixed muscle weakness as opposed to cramps and myoglobinuria (227–229), and (5) presentation as hereditary nonspherocytic hemolytic anemia without muscle symptoms (230). Late-onset PFK deficiency may lead to thickening of the mitral valve as a result of glycogen build-up (231).

Characteristics that may differentiate type VII from type V are as follows: (a) earlier age of onset of exercise intolerance and more acute symptoms than in type V; (b) a rise in serum bilirubin levels and reticulocyte counts that marks the onset of compensated hemolytic anemia; (c) hyperuricemia is common and more aggravated by muscle employment than in GSD V or III (232); (d) muscle fibers contain an abnormal polysaccharide that is periodic acid-Schiff-positive but resistant to diastase digestion (233,234); and (e) exercise is particularly intolerable after carbohydrate-rich meals (235).

**93.10.3.2 Biochemical Aspects.** Laboratory studies show elevation of muscle enzyme values (aldolase, creatine kinase, lactate dehydrogenase, and oxaloacetate transaminase) and uric acid in the serum. The reticulocyte count is mildly increased, but the hemoglobin level may be normal. Muscle fibers show increased glycogen content and vacuolar and degenerative changes. PFK activity is absent in muscle and reduced in erythrocytes. The PFK molecule is a tetramer. Three subunits exist: muscle (M), liver (L) and platelet (P). The muscle isozyme is composed of four identical (M) subunits, whereas erythrocyte PFK is made up of M and L subunits. In PFK deficiency, the M subunit is absent and the residual PFK

activity in erythrocytes reflects the presence of the L subunit, which is about 50% of normal.

**93.10.3.3 Treatment.** Until recently, the only means of managing PFK deficiency was the avoidance of strenuous exercise. Patients should avoid drugs such as statins. When undergoing anesthesia, precautionary measures to avoid malignant hyperthermia should be taken. Unlike in GSD V, carbohydrate meals and glucose infusions can worsen symptoms in GSD VII. The problem is two-fold in PFK deficiency: glucose cannot be utilized in type VII muscle due to enzymatic block, and the administered glucose actually lowers blood levels of fatty acids—the primary source of muscle fuel. Of late, significant clinical improvement was seen in a child with the severe infantile form of PFK deficiency following the initiation of a ketogenic diet (236).

**93.10.3.4 Genetic Aspects.** PFK deficiency is rare. It is inherited as an autosomal recessive disorder. The gene for the M subunit is on chromosome 1. Around 20 mutations have been reported, including frameshift, missense, and splicing defects (237). There does not appear to be a prevalence of PFK deficiency in any particular ethnic group, although two common mutations—a nucleotide deletion and an exon 5 splicing defect—frequently affect those of Ashkenazi Jewish descent. In this population, 95% of Tarui disease cases are attributed to these two mutations (238). The gene for the L subunit is located at 21q22.3.

### 93.10.4 Muscle Phosphoglucomutase Deficiency

Glycogen accumulation in skeletal muscle has been reported in several infants and children. The clinical picture is variable. One infant had features associated with Reye's syndrome, such as nonketotic dicarboxylic aciduria and hypoglycemia associated with systemic carnitine deficiency. However, a case of adult-onset muscle phosphoglucomutase appeared in a 38-year-old male patient who presented with muscle weakness, clubbed fingers, and hypesthesia of distal extremities (239). Another 35-year-old male with muscle phosphoglucomutase deficiency was identified by his exercise-induced muscle weakness, normal lactate levels, episodic rhabdomyolysis, and elevated ammonia release when given a forearm-exercise test (240).

### 93.10.5 Muscle Phosphorylase Kinase Deficiency

**93.10.5.1 Clinical Aspects.** Introduced in the section GSD Type IX, muscle PhK deficiency, caused by mutations in the X-linked *PHKA1* gene, presents from childhood to adulthood with variable symptoms including muscle cramps and myoglobinuria on exercise, and progressive muscle weakness and atrophy (156). An adult male with asymptomatic myopathy and cognitive

impairment has also been reported. However, it is not known whether the cognitive impairment in this patient is due to the muscle PhK deficiency or has another cause (241). Electromyography and forearm ischemic exercise test are usually normal. Involvement of heart and liver has not been reported in individuals with *PHKA1* mutations. Infants with PhK deficiency in muscle and fatal arthrogryposis and severe hypotonia, without organomegaly, have also been reported. Molecular analysis has not been performed and thus it is unknown whether the PhK deficiency in these cases was caused by mutation of gene encoding a PhK subunit expressed in muscle (such as *PHKA1* or *PHKG1*) or has another cause.

**93.10.5.2 Biochemical Aspects.** The PhK enzyme is composed of four subunits (see liver phosphorylase kinase deficiency). In muscle, the alpha subunit is encoded by the *PHKA1* gene on chromosome Xq13, the beta subunit is encoded by the *PHKB* gene which is alternatively spliced in liver and muscle and located on chromosome 16q12–q13, the gamma subunit is encoded by the *PHKG1* gene on chromosome 7p12–p21, and the delta subunit is calmodulin. In muscle PhK deficiency, subsarcolemmal glycogen accumulation and marked reduction of PhK activity are observed in muscle biopsy samples. Serum creatine kinase may be above normal.

**93.10.5.3 Genetic Aspects.** Mutations causing skeletal muscle PhK deficiency have only been found in the *PHKA1* gene. However, mutations in this gene are found in only a small number of individuals with muscle PhK deficiency suggesting other genetic or metabolic causes, or false positive results (242). Rare cases of infants with severe isolated cardiomyopathy and PhK deficiency in heart muscle have been reported. Mutations in the *PRKAG2* gene, encoding the regulatory subunit of AMP-activated protein kinase have been identified in some of these individuals (243,244). No mutations in genes encoding any of the PhK subunits have been found in these cases (see glycogen storage diseases mimicking hypertrophic cardiomyopathy).

**93.10.5.4 Treatment.** Individuals with muscle PhK deficiency may benefit from physical therapy and nutritional consult to optimize glucose concentrations based on level of activity. Malignant hyperthermia precautions should be taken.

### 93.10.6 Other Muscle Glycogenoses

Six additional enzyme defects produce muscle glycogenoses, namely, deficiencies in phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, fructose-1,6-bisphosphate aldolase A, pyruvate kinase, and  $\beta$ -enolase. All six enzyme defects cause symptoms and signs of muscle energy impairment similar to those of the types V and VII GSD. The failure of blood lactate to increase in response to exercise is a useful diagnostic test and can be used to differentiate muscle glycogenoses

from disorders of lipid metabolism, such as carnitine palmitoyl transferase II deficiency and very long chain acyl-CoA dehydrogenase deficiency, which also cause muscle cramps and myoglobinuria. Muscle glycogen levels may be normal in the disorders affecting terminal glycolysis, and definite diagnosis is made by assaying the muscle enzyme activity. There is no specific treatment. Avoidance of strenuous exercise prevents acute attacks of muscle cramps and myoglobinuria.

### 93.10.7 Muscle Glycogen Synthase Deficiency

GSD due to muscle glycogen synthase (glycogen synthase I, GYS1) deficiency has been reported in four children, three from one family. The first child, an 8-year-old south Indian boy of consanguineous parents, presented with muscle glycogen synthase deficiency when he collapsed during muscular exertion and died soon thereafter due to cardiac failure. Mutational analysis revealed a double base pair deletion in exon 2 of GYS1 and autopsy revealed oxidative compensation and a large population of mitochondria (245). In the second family, the three children (two boys and one girl) of consanguineous Syrian parents all had cardiac involvement. The oldest of the three siblings collapsed at age 10.5 years from sudden cardiac death, the second boy exhibited muscle fatigability, heart arrhythmia, hypertrophic cardiomyopathy, and hypotension during exertion, and the youngest showed slight resting cardiac malfunction. Although glycogen was lacking in the muscle biopsies, the two surviving children showed normal glucose tolerance (246).

## 93.11 GSD PRIMARILY WITH CARDIAC INVOLVEMENT

### 93.11.1 GSDs Mimicking Hypertrophic Cardiomyopathy

**93.11.1.1 Clinical Aspects.** Glycogen can amalgamate in heart and skeletal muscle due to malfunctioning of lysosomal associated membrane 2 protein (LAMP2, classified as Danon's disease) and AMP-activated kinase gamma 2 protein (PRKAG2). Patients with LAMP2 deficiency suffer with chest pain, heart palpitations, syncope, and cardiac arrest usually between 8 and 15 years of age. Although patients with PRKAG2 defects experience similar cardiac symptoms, they usually occur at the much later average age of 33 years. Earlier age of presentation has been reported in a study where the range of onset for patients with PRKAG2 gene defects spanned from 9 to 55 years of age (247). In addition, a congenital, rapidly fatal, fetal symptomatic onset presentation with hypertrophic cardiomyopathy with Wolff-Parkinson-White (WPW) syndrome, caused by PRKAG2 mutations, has been noted (243).

**93.11.1.2 Biochemical Aspects.** Electrophysiologic abnormalities in sarcomere proteins, namely ventricular preexcitation and conduction defects, differentiate hypertrophic cardiomyopathy caused by LAMP2 and PRKAG2 mutations from other causes (248–251). PRKAG2 functions as an enzymatic regulator of glucose absorption, glycolysis, and fatty acid metabolism. The deficiency causes myocytes to have abnormally high numbers of vacuoles replete with glycogen. In a yeast model, mutational analysis of the homologous gene *Snf4* revealed overactive AMP kinase, possibly promoting glycogen buildup (250). In humans, this phenomenon is explained by the AMPK feedback loop being constantly activated, which in turn consistently draws more energy metabolites than needed, resulting in excess glycogen storage.

**93.11.1.3 Treatment.** The two deficiencies have differing prognoses: LAMP2 deficiency tends to lead to worsening heart complications and eventual cardiac arrest in young adult patients, whereas life with PRKAG2 deficiency is sustainable given pacemaker implantation and vigilant arrhythmia monitoring. The several infants with severe congenital PRKAG2 deficiency generally succumbed to the acute hypertrophic cardiomyopathy.

**93.11.1.4 Genetic Aspects.** Mutations responsible for Danon's disease are X-linked while those causing PRKAG2 deficient are autosomal dominant. Two mutations causing the congenital form of PRKAG2 that are incompatible with life (p.Arg531Gln and p.Arg384Thr) cause higher levels of AMPK phosphorylation and therefore higher basal levels of activity, although AMP and ATP binding is reduced. Other mutations responsible for adult-onset hypertrophic cardiomyopathy (p.Arg302Gln, p.Thr400Ans, and p.Asn488Ile, p.His487Tyr) and WPW syndrome cause less disruptive molecular changes (243,244). In three of five cases originating from different geographic regions, three equivalent but separate heterozygous p.Arg531Gln missense mutations were discovered in PRKAG2. This mutation is responsible for severe clinical manifestations including: fetal onset (all three patients experienced prenatal bradycardia, necessitating cesarean section preterm delivery; one had prenatal cardiomegaly), extreme cardiomegaly, and infantile-fetal outcome. The three patients with the p.Arg513Gln mutation died due to hemodynamic and respiratory failure, with additional complications including hypertrophic nonobstructive cardiomyopathy and conduction abnormalities seen in WPW syndrome (243). It should be noted, however, that patients with nonfamilial WPW syndrome may not always have the PRKAG2 genetic defect (252).

### 93.11.2 Animal Models of GSD

Several GSDs with inheritance patterns similar to those in humans have been identified in animals. These include GSD type Ia in mice (253,254) and dog (255), GSD II ( $\alpha$ -glucosidase deficiency) in mice (256), Japanese quail

(257) and Australian cattle, GSD III in dog (258), GSD IV in cat (259), GSD V in cattle and sheep (260,261), GSD VII in dog (262), liver PhK deficiency in rats (263), muscle PhK deficiency in mice (264), PhK deficiency in rats (265), and PRKAG2 defects in mice (266).

## 93.12 GLUCONEOGENIC DISORDERS ASSOCIATED WITH LACTIC ACIDOSIS

### 93.12.1 Metabolism

The maintenance of carbohydrate homeostasis in the human body is a complex process and involves the interaction of many factors. In fasting conditions, blood glucose is derived mainly from glycogen breakdown (glycogenolysis) and from the conversion of lactic acid and certain amino acids to glucose (gluconeogenesis).

Gluconeogenesis takes place primarily in the liver and kidneys. The metabolic process is in part under endocrine control. During a prolonged fast, the levels of glucocorticoids may be increased. These hormones increase the synthesis of pyruvate carboxylase, G6Pase, and aminotransferases, participants in the gluconeogenic pathway. Gluconeogenic amino acids, such as alanine, aspartic acid, and glutamic acid are converted to pyruvate, oxaloacetate, and alpha-ketoglutarate, respectively, and subsequently feed into the pathway culminating in the formation of glucose (Figure 93-7).

During fasting, epinephrine and glucagon increase, accelerating the glycogenolytic process through the activation of adenyl cyclase. At the other end of the glycolytic pathway, pyruvate kinase is inactivated by a

cAMP-dependent protein kinase, diminishing the conversion of triose phosphate to pyruvate and lactate.

In addition to pyruvate kinase, gluconeogenesis is also tightly regulated by other key enzymes that are sensitive to allosteric control. Pyruvate carboxylase, which plays a primary role in the conversion of pyruvate to oxaloacetate, is activated by acetyl CoA. When excess acetyl CoA builds up in cells, glucose synthesis is enhanced. Phosphoenolpyruvate carboxykinase is also necessary for phosphoenolpyruvate formation from oxaloacetate.

Other key enzymes in regulating the gluconeogenic pathway are fructose-1,6-diphosphatase and G6Pase. Fructose-1,6-diphosphatase is stimulated by citrate and inhibited by AMP. G6Pase and fructose-1,6-diphosphatase are known to be present in liver and intestinal tissues, whereas pyruvate carboxylase and phosphoenolpyruvate carboxykinase have been shown to be present also in other tissues, including cultured skin fibroblasts. Genetic defects have been encountered in each of these enzymes in humans. Hypoglycemia and lactic acidosis are the most common findings. Lactic acidosis, secondary to hypoxia, shock or sepsis is not an uncommon complication in sick infants and children. Mitochondrial damage observed in Reye's syndrome leads to lactic acidosis. Whatever the cause, persistent lactic acidosis usually needs prompt medical attention. The ratio of blood lactate to pyruvate can be useful in the differential diagnosis of lactic acidosis. A normal ratio of 10:20 with high lactate content suggests the possibility of defects in pyruvate metabolism, whereas a high ratio of more than 20:30 suggests defects in the tricarboxylic acid cycle or mitochondrial disorders, many of which can be diagnosed by molecular mutations or enzyme assays.

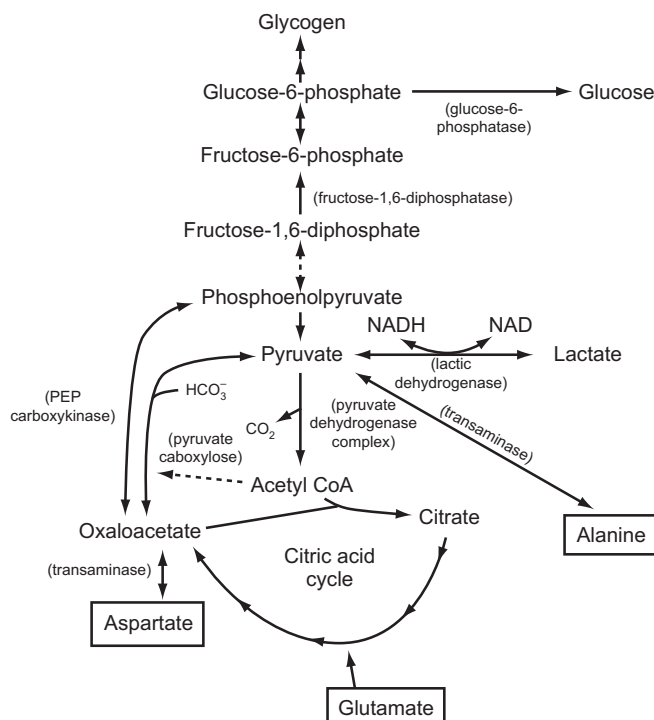

FIGURE 93-7 The gluconeogenic pathways.

### 93.12.2 Fructose-1,6-Diphosphatase Deficiency

**93.12.2.1 Clinical Aspects.** Symptoms usually begin in early infancy with hypoglycemia, hyperlactic acidemia, and ketoacidosis (267). Hypoglycemia occurs when glycogen reserves are limited or exhausted. The onset of symptoms often follows an infection. In some patients, the onset is delayed and the clinical picture is similar to that of ketotic hypoglycemia. With age, the frequency of hypoglycemia attacks decreases. The most common physical finding is hepatomegaly, resulting from fatty metamorphosis. Despite the metabolic defect, growth and intellectual development may proceed normally. Fructose-1,6-diphosphatase deficiency may be confused with GSD type I because of similarity of clinical features and laboratory findings of hypoglycemia and increased blood lactic acid. It differs from HFI in that patients usually have no aversion to sweets as well as normal renal tubular and liver functions. Confirmation of diagnosis is based on the measurement of fructose-1,6-diphosphatase activity in liver tissue or mutation analysis.

**93.12.2.2 Biochemical Aspects.** Fructose-1,6-diphosphatase is the key regulator of gluconeogenesis, during which it catalyzes the hydrolysis of fructose-1,6-bisphosphate to fructose-6-phosphate and inorganic phosphate. This enzyme is expressed in several tissues with maximum activity in the liver and kidney. Prolonged fasting in the affected patient induces severe hypoglycemia, lactic acidosis, and hyperalaninemia. The ingestion of glycerol, fructose, and alanine produces hypoglycemia, an increase in lactate, and a fall in serum inorganic phosphate. Serum uric acid may also increase. The glycemic response to glucagon and galactose administration has been variable. Lactate, pyruvate, beta-hydroxybutyrate, alpha-ketoglutarate, and glycerol-3-phosphate accumulate in the urine (268). Fructose-1,6-diphosphatase is normally present in liver, kidney, and intestinal tissue. It has also been found in muscle, platelets, and lymphocytes; however, the usefulness of these cells for diagnostic purposes has not been established. Enzyme assay in cultured monocytes rather than isolated leukocytes was shown to be of accurate diagnosis of fructose-1,6-diphosphatase deficiency (269).

Successful pregnancy outcome has been reported in one case of a woman with fructose-1,6-diphosphatase deficiency. After the birth of her three children, this patient began to experience auditory and cognitive difficulties (270).

**93.12.2.3 Treatment.** Treatment consists of frequent feedings and avoidance of extended fasting periods in order to prevent hypoglycemia and limiting fructose and sorbitol intake. It has been suggested that folic acid may increase synthesis of fructose-1,6-diphosphatase (271).

**93.12.2.4 Genetic Aspects.** Fructose-1,6-diphosphatase deficiency is a rare condition inherited as an autosomal recessive trait. In parents of affected children, intermediate values of enzyme activity were found in the liver (272,273) and in cultured lymphocytes (274). The cDNA for fructose-1,6-diphosphatase has been cloned, and the gene is localized to chromosome 9q22–q22.3 (275). Several mutations have been identified in affected patients (275,276).

### 93.12.3 Pyruvate Carboxylase Deficiency

**93.12.3.1 Clinical Aspects.** Clinical manifestations usually appear soon after birth. Metabolic acidosis due to lactic acid, failure to thrive, hypotonia, anorexia, and hyporeflexia have been observed. Death within 1–2 months of age may occur. Patients surviving the initial problems exhibit retarded growth, seizures, hypotonia, and continuing metabolic acidosis. Three forms have been described thus far: Type A (infantile or North American form), Type B (neonatal or French form) and Type C (benign form). These phenotypes constitute a continuum spanning from the most severe (Type B) to the least severe form (Type C). Laboratory findings include severe lactic acidosis, ketonemia, with normal

lactate/pyruvate ratio (exception is type B) and, in some cases, hyperammonemia, citrullinemia, hyperlysinemia and hypoglycemia (277). Mosaicism may correlate with longer life span (278).

**93.12.3.2 Biochemical Aspects.** Pyruvate carboxylase (PC) is a biotin-containing enzyme that catalyzes the formation of oxaloacetate in the presence of an allosteric activator, acetyl CoA, from pyruvate. In this process called anaplerosis, the synthesis of oxaloacetate functions to replenish the stores of intermediates depleted during metabolism but required for the citric acid cycle (CAC). Not only is PC critical in this reaction, it plays a critical role in conjunction with oxaloacetate in gluconeogenesis, glycogen synthesis, lipogenesis, glycerogenesis, amino acid and neurotransmitter synthesis, and glucose-dependent insulin secretion (277). The enzyme deficiency has been demonstrated in liver tissue, leukocytes, and cultured skin fibroblasts. The enzyme activity is intermediate in known carriers (277,279). The enzyme is also present in cultured amniotic cells, and prenatal diagnosis has been accomplished (277).

**93.12.3.3 Treatment.** Drastic supportive measures are usually needed. Metabolic acidosis (lactic acidosis) should be treated promptly. Peritoneal dialysis, intravenous fluids with glucose, and general hydration may be helpful in reversing the clinical consequences of the metabolic defects (280). Biotin, thiamine and lipoic acid have been used in some patients, as well as inclusion of glutamine and aspartic acid with questionable benefit (281). Anaplerotic treatment research focuses on restoration of necessary intermediates in the CAC that are undermined by the detrimental effects of pyruvate carboxylase deficiency, and with restorative treatment, the cycle can continue creation of ATP (277,282). Orthotopic liver transplantation has been successful in a couple of cases (280). Fasting and the ketogenic diet should be avoided.

**93.12.3.4 Genetic Aspects.** PC deficiency is inherited as an autosomal recessive disorder. The frequency of occurrence is not known. In two patients who presented with hyperammonemia, there was no cross-reacting material, whereas other patients had shown immunoprecipitated proteins (283). The cDNA for PC has been cloned, and the gene is located on chromosome 11q13.4–q13.5 by somatic hybridization (280,284). At this time, 15 mutations have been identified (285). In the study done by Wang et al., the genotype–phenotype correlations were characterized: type A was caused by mutations p.Arg62Cys, p.Arg631Gln, p.Ala847Val, p.Val145Ala, p.Arg451Cys, p.Ala610Thr and p.Met743Ile; type B was caused by a variety of missense, deletion, and splice donor site mutations; and type C was caused by either a heterozygous p.Ser266Ala mutation with a p.Ser705X mosaicism or heterozygous p.Thr569Ala and p.Leu1137ValfsX1170 mutations (278). In one study, individuals of Ojibwa and Cree backgrounds tended to have a homozygous p.Ala610Thr missense

mutation (founder effect) and two brothers of Micmac origin presented with a p.Met743Ile transversion mutation (286).

### 93.12.4 Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (PEPCK) deficiency is a rare disease and there appear to be two isoforms: cystolic (PEPCK 1) and mitochondrial (PEPCK 2). Only a few patients have been described. The patients with PEPCK 1, influenced by induction of catabolic states and repressed by anabolic states, can suffer with hepatomegaly, hypoglycemia, hyperinsulism, hypertriglyceridemia, and hypercholesterolemia (287,288). Those with PEPCK 2 suffer with hypotonia, hypoglycemia, lactic acidemia, and failure to thrive (288). In one patient, the activity of PEPCK in cultured skin fibroblasts was found to be 17% of the controls in whole cells and 6% in isolated mitochondria (289). Both human hepatic mitochondrial and cystolic PEPCK enzyme cDNA have been isolated (290).

### 93.12.5 Deficiencies of Pyruvate Dehydrogenase Complex

**93.12.5.1 Clinical Aspects.** The extremely variable clinical expression in this group suggests both clinical and biochemical heterogeneity. Patients have been described with one or more of the following findings: microcephaly, slow mental and physical development, seizures, hypotonia, optic atrophy of variable degree, cerebellar ataxia, and severe lactic acidosis. Neurological manifestations can be categorized into two groups: the first, abnormal brain development seen in both males and females, and the second, brain lesions and epilepsy seen only in male patients (291). Neonatal form of PDHC deficiency is severe, and patients usually die within a few months of life. In some patients, postmortem examination revealed specific CNS pathology of Leigh's disease (292). Partial deficiency of the enzyme complex has also been observed in patients with spinocerebellar degeneration and in Friedreich's ataxia (293). Patients with pyruvate dehydrogenase complex (PDHC) deficiency usually do not have hypoglycemia.

**93.12.5.2 Biochemical Aspects.** PDHC comprises three principal enzymes (E1, pyruvate dehydrogenase or pyruvate decarboxylase; E2, dihydrolipoyl transacetylase; and E3, dihydrolipoyl dehydrogenase), and five different coenzymes (thiamine pyrophosphate, lipoic acid, coenzyme A, flavin adenine dinucleotide, and nicotinamide adenine dinucleotide). In addition, a specific kinase for inactivation and a phosphatase for activation of the pyruvate dehydrogenase have been demonstrated, as well as protein X (294). The E1 component is a tetramer containing a 41-kDa and 36-kDa subunit.

The sequence of the PDHC reactions can be simplified as follows (295):

Pyruvate dehydrogenase is composed of four subunits: two E1 alpha and two E1 beta. The alpha subunit is X-linked. Because of the complexity of this enzyme system, it is important to have reliable methods for the enzyme assays to pinpoint the basic defect. PDHC activity is present in cultured skin fibroblasts, and therefore, these cells are a good source for enzyme diagnosis. Caution is needed to avoid mycoplasma contamination because an unusually large amount of pyruvate dehydrogenase activity has been demonstrated in contaminated cultures (296).

In patients with PDHC deficiency, the levels of pyruvate, lactate, and alanine are increased in blood and urine. In milder cases, random samples of blood or urine may show normal amounts of lactate. Oral glucose loads or high carbohydrate intake may induce elevations in blood lactic acid and aggravate the symptoms. Two brothers with pyruvate dehydrogenase deficiency showed absent to trace amounts of both the E1 alpha and beta subunits in liver, skeletal muscle, and heart (297). The lymphocytes had enzyme activity about 10% of normal controls, whereas the activity in cultured skin fibroblasts was normal. Both patients had abnormal neuromuscular development and lactic acidosis. Isolated dihydrolipoyl dehydrogenase (lipoamide dehydrogenase) deficiency has been reported in which patients presented lactic acidosis and ketosis with neurologic abnormality. However, this deficiency appeared to be more common among the Ashkenazi Jewish population (298). A recent study shows how the reactive oxygen species generated by the mutations responsible for lipoamide dehydrogenase deficiency may in fact explain certain disease characteristics as well as proffer the prospect of antioxidant therapy (299).

**93.12.5.3 Treatment.** In general, administration of thiamine or lipoic acid, or both, has not been helpful in most cases. Intravenous glucose should be administered with caution because it can cause severe lactic acidosis. It is recommended that patients should follow a ketogenic diet, high in fats and low in carbohydrates (300). Although this diet may be helpful in saving the patient's life, it has not prevented mental deterioration in severe cases. In patients identified as having dihydrolipoyl dehydrogenase deficiency, favorable responses to lipoic acid treatment (301) and to branched-chain amino acid restriction have been observed (302).

**93.12.5.4 Genetic Aspects.** Because several enzymes and cofactors are involved, the specific biochemical and genetic causes of pyruvate dehydrogenase deficiency

should be demonstrated so as to ascertain the particular mode of inheritance. The frequency of occurrence of PDHC deficiencies may be more than as is now realized. Any patient who has died as a result of lactic acidosis should be considered a possible victim of the condition. Prenatal diagnosis, at least in some cases, should be possible because the enzyme system is present in cultured amniotic cells. Isolation of cDNA clones for various enzyme components of the PDHC has been recently reported. Pyruvate dehydrogenase itself has a tetrameric structure with alpha and beta subunits. The gene for E1 alpha subunit, *PDHA1*, is located on chromosome Xp22.1 (303,304). The most common defects are in the alpha subunit. Several mutations have been described in affected male and female patients (305,306). A mutation in the mitochondrial targeting sequence was identified in an affected family (307). The patient having a mutation (p.Phe205Leu) in the E1 alpha subunit responded to thiamin treatment because the enzyme showed impaired binding of the thiamin diphosphate cofactor (308). One boy with a c.857C>T (p.Pro250Leu) mutation had hypotonia and psychomotor retardation since infancy. Another boy with a c.367C>T (p.Arg88Cys) mutation showed symptoms, including seizures, starting at the toddler age and progressed to dystonia and myopathy with normal psychomotor development by 7 years (309). The gene for the beta subunit of E1 is located on chromosome 3p21.1–1p4.2 (311). Mutations (homozygous p.Met101Thr, and heterozygous p.Arg105Gln and p.Met101Val) on the beta subunit of E1 have caused a couple of patients to present with Leigh's disease (310). Mutations for E3 binding protein (protein X) of the PDHC have been characterized in two siblings in each of two unrelated families from Kuwait (312). A common mutation of lipoamide dehydrogenase deficiency (p.Gly194Cys) was found in both Arab Muslim and Ashkenazi Jewish patients (313).

## ACKNOWLEDGMENTS

We thank Alexandra Beckemeyer for her assistance with the literature searches and formatting of the book chapter. We also thank Jennifer Goldstein and Karen Corneliussen for their help with proofreading the chapter.

### Biographies

**Dr Priya S Kishnani, MD**, throughout her career primarily focused on the translation of laboratory science into the clinical arena, especially in the area of such therapeutic interventions as enzyme replacement therapy and small molecules. The care, treatment and natural history of individuals with lysosomal storage disorders (LSDs), glycogen storage diseases (GSDs), Down syndrome (DS) and other inborn errors of metabolism remain her passions. Her areas of publication include treatment strategies, examination of long-term complications and the results of a number of clinical trials for multiple disorders. She has a long-standing research and clinical interest in Pompe disease and, since 1999, has been the principal investigator for several clinical trials involving Pompe disease which resulted in FDA approval of Myozyme as the first treatment for this otherwise lethal neuromuscular disease in 2006. She has placed an emphasis on continued care for these chronic conditions via a multidisciplinary team approach. At Duke University Hospital where Dr Kishnani serves as a professor of Pediatrics and the Chief of Medical Genetics, her primary clinical responsibilities involve the care for individuals with GSDs (with a research interest in Types I, II, III and IX), LSDs, other inborn errors of metabolism and Down syndrome.

**Professor Yuan-Tsong (Y-T) Chen** received his MD degree from National Taiwan University (Taipei) and PhD from Columbia University (USA). He is currently a Distinguished Research Fellow of the Institute of Biomedical Sciences, Academia Sinica, Taiwan, and professor of Pediatrics at Duke University Medical Center (USA). Professor Chen is a physician/scientist, recognized for his work on human genetic disorders. His translational research leads to the development of new standard therapies for two devastating inherited metabolic diseases: a simple and effective cornstarch therapy for severe hypoglycemia in glycogen storage diseases and an enzyme replacement therapy, the first ever treatment, for a debilitating, progressive and often fatal myopathy called Pompe disease. Professor Chen has also identified the genetic basis of and developed DNA-based diagnosis for several major heritable diseases, and more recently, uncovered genes/SNPs associated with drug-induced Stevens–Johnson syndrome and warfarin sensitivity. Professor Chen is an elected member of Academia Sinica and of the Academy Sciences for the Developing World.

## Congenital Disorders of Protein Glycosylation

*Jaak Jaeken*

Center for Metabolic Diseases, University Hospital Gasthuisberg, Leuven, Belgium

### 94.1 NORMAL PROTEIN GLYCOSYLATION

Congenital disorders of glycosylation (CDGs) are a rapidly growing family of genetic diseases due to defects in the synthesis of the glycan moiety of glycoproteins and glycolipids. This chapter is limited to genetic defects of protein glycosylation (1–3).

There are two main types of protein glycosylation: N-glycosylation and O-glycosylation. N-glycosylation comprises an assembly part and a processing part, and extends over three cellular compartments: the cytosol, the endoplasmic reticulum (ER), and the Golgi. The assembly part of the N-glycosylation starts on the cytosolic side of the ER with the transfer of N-acetylglucosamine (GlcNAc) phosphate from UDP-GlcNAc to membrane-bound dolichyl monophosphate (Dol-P), forming GlcNAc-pyrophosphatedolichol (GlcNAc-PP-Dol). One GlcNAc and five mannose (Man) residues are subsequently attached to this lipid-linked monosaccharide in a stepwise manner. The donor of these mannoses is a nucleotide-activated sugar, GDP-Man, which is synthesized from fructose 6-phosphate, an intermediate of the glycolytic pathway. The lipid-linked heptasaccharide  $\text{Man}_5\text{GlcNAc}_2$  is translocated by a flippase across the ER membrane and, at the luminal side, is elongated by the attachment of four more mannose residues and, subsequently, of three glucose residues. The four mannosyltransferases and three glucosyltransferases involved require dolichyl phosphate-bound monosaccharides (Dol-P-Man and Dol-P-Glc). The completed  $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$  oligosaccharide is then transferred to selected asparagine residues of the nascent proteins by the oligosaccharyltransferase complex.

The processing part of the N-glycosylation starts in the ER by trimming off of the glucoses (catalyzed by glucosidases I and II) and one mannose (catalyzed by mannosidase I). The residual glycoprotein intermediate is directed to the cis-Golgi, where the processing pathway branches. A

minor branch targets glycoproteins to the lysosomes (after the action of a GlcNAc-phosphotransferase and removal of the GlcNAc residues, leaving high-mannose glycoproteins capped with Man 6-P). The main branch leads to further trimming of mannoses (leaving a trimannosyl core) and addition of respectively GlcNAc, galactose, and eventually, sialic acid in the medial- and trans-Golgi, respectively. Another modification of many N-glycoproteins in the Golgi is the attachment of fucose to the GlcNAc residue that is linked to asparagine. O-glycosylation (O-glycans attached to the hydroxyl group of threonine or serine of proteins) has no processing part and thus consists only of assembly. Contrary to N-glycosylation, this assembly mainly occurs in the Golgi. O-glycan structures show a greater diversity than N-glycans. Examples of important O-glycans are O-N-acetylgalactosaminylglycans (mucin-type glycans), O-xylosylglycans (glycosaminylglycans), and O-mannosylglycans.

Genetic defects of protein glycosylation can be divided into three classes: disorders of protein N-glycosylation, disorders of protein O-glycosylation, and combined disorders of protein N- and O-glycosylation.

In 2008–2009, a novel nomenclature of the CDG was introduced, namely, the official gene symbol (not in italics) followed by “-CDG” (4,5). A list of approved gene names can be found at <http://www.genenames.org>. The novel nomenclature is used in this chapter.

### 94.2 CONGENITAL DISORDERS OF PROTEIN N-GLYCOSYLATION

Eighteen disease-causing defects are known in protein N-glycosylation: 14 assembly defects (in pre-ER and ER) and 4 processing defects (in ER and Golgi) (Table 94-1). The four most frequent disorders (PMM2-CDG, MPI-CDG, ALG6-CDG and ALG1-CDG) are described in more detail, as well as the first N-glycan processing defect (MGAT2-CDG) and the first deafness CDG (RFT1-CDG).

**TABLE 94-1 Genetic Protein N-Glycosylation Disorders**

Disorder	Affected Protein	Defective Gene	OMIM Number
PMM2-CDG	Phosphomannomutase 2	<i>PMM</i>	212065
MPI-CDG	Phosphomannose isomerase	<i>MPI</i>	602579
ALG6-CDG	Glucosyltransferase 1	<i>ALG6</i>	603147
ALG3-CDG	Mannosyltransferase 6	<i>ALG3</i>	601110
ALG12-CDG	Mannosyltransferase 8	<i>ALG12</i>	607143
ALG8-CDG	Glucosyltransferase 2	<i>ALG8</i>	608104
ALG2-CDG	Mannosyltransferase 2	<i>ALG2</i>	607906
DPAGT1-CDG	UDP-GlcNAc:DoI-P-GlcNAc-P-transferase	<i>DPAGT1</i>	608093
ALG1-CDG	Mannosyltransferase 1	<i>ALG1</i>	608540
ALG9-CDG	Mannosyltransferase 7-9	<i>ALG9</i>	608776
ALG11-CDG	Mannosyltransferase 4-5	<i>ALG11</i>	613611
RFT1-CDG	Flippase of Man <sub>5</sub> GlcNAc <sub>2</sub> -PP-DoI	<i>RFT1</i>	612015
TUSC3-CDG	Oligosaccharyltransferase tusc3	<i>TUSC3</i>	611093
MAGT1-CDG	Magnesium transporter 1	<i>MAGT1</i>	300716, 300853
GCS1-CDG	Glucosidase 1	<i>GCS1</i>	606056
MAN1B1-CDG	Mannosidase 1B1	<i>MAN1B1</i>	614202
MGAT2-CDG	N-acetylglucosaminyltransferase 2	<i>MGAT2</i>	212066
ST3GAL3-CDG	Beta-galactoside-alpha-2,3-sialyltransferase 3	<i>ST3GAL3</i>	611090

### 94.2.1 PMM2-CDG (Phosphomannomutase 2 Deficiency)

This is, by far, the most frequent protein N-glycosylation disorder (approximately 700 patients known) (6). The clinical spectrum is very broad: The nervous system is affected in all patients, and most other organs are involved in a variable way. The neurologic picture comprises alternating internal strabismus and other abnormal eye movements, axial hypotonia, psychomotor retardation, ataxia, and hyporeflexia. After infancy, symptoms include retinitis pigmentosa, often stroke-like episodes, and sometimes, epilepsy. As a rule, there is no regression. During the first years of life, there are variable feeding problems (e.g. anorexia, vomiting, diarrhea) that can result in severe failure to thrive. Other features are a variable dysmorphism (e.g. large, hypoplastic/dysplastic ears), abnormal subcutaneous adipose tissue distribution (e.g. fat pads, inverted nipples), mild to moderate hepatomegaly, skeletal abnormalities, and hypogonadism. Some infants develop pericardial effusion or cardiomyopathy, or both. At the other end of the clinical spectrum are patients with a very mild phenotype (no dysmorphism, slight psychomotor retardation). Patients often have an extroverted and happy appearance. There is a substantially increased mortality rate in the first years of life due to severe infection or vital organ involvement. Neurotechnical investigation reveals (olivoponto)-cerebellar hypoplasia, variable cerebral hypoplasia, and peripheral neuropathy. Liver pathology is characterized by fibrosis and steatosis, and electron microscopy shows myelin-like lysosomal inclusions in hepatocytes but not in Kupffer cells.

Phosphomannomutase 2 deficiency is a (cytosolic) defect in the second step of the mannose pathway (transforming mannose 6-phosphate into mannose

1-phosphate), which normally leads to the synthesis of guanosine diphosphate (GDP)-mannose. This nucleotide sugar is the donor of mannose used in the ER to assemble the dolichyl-pyrophosphate oligosaccharide precursor. Deficiency of GDP-mannose causes hypoglycosylation (and hence, deficiency, increase and/or dysfunction) of numerous glycoproteins, including serum proteins, lysosomal enzymes, and membranous glycoproteins.

The diagnosis of PMM2-CDG (and of congenital disorders of N-glycosylation in general) is usually made by isoelectrofocusing (IEF) and immunofixation of serum transferrin. Normal serum transferrin is mainly composed of tetrasialotransferrin and small amounts of mono-, di-, tri-, penta- and hexasialotransferrins. The partial deficiency of sialic acid (a negatively charged and an end-standing sugar) in CDG causes a cathodal shift. Two main types of cathodal shift can be recognized: type 1 is characterized by an increase of both disialo- and asialotransferrin and a decrease of tetra-, penta-, and hexasialotransferrins; in type 2, there is also an increase of the tri- and/or monosialotransferrin bands. In PMM2 deficiency, a type 1 pattern is found. First, a shift due to a transferrin protein variant has to be excluded (IEF after neuraminidase treatment, study of the parents, study of another glycoprotein). Recently, capillary zone electrophoresis of total serum has been introduced for the diagnosis of CDG.

In addition to the aforementioned serum glycoprotein abnormalities, laboratory findings include elevation of serum transaminase levels, hypoalbuminemia, hypocholesterolemia, and tubular proteinuria. To confirm the diagnosis, the activity of PMM2 should be measured in leukocytes or fibroblasts. Prenatal diagnosis is possible by enzymatic analysis of amniocytes and chorionic villus cells; this should be combined with mutation analysis of the *PMM2* gene.

Treatment is only symptomatic. Low-dose acetylsalicylic acid can be effective in the prevention of recurrent strokes.

PMM2-CDG is an autosomal-recessive disease. At least 100 mutations have been identified (mainly missense mutations). The most frequent mutation causes the R141H protein change.

### 94.2.2 MPI-CDG (Phosphomannose-Isomerase Deficiency)

Some 45 patients have been reported or are known to the author with phosphomannose-isomerase deficiency (MPI-CDG). It is mainly a hepatic-intestinal disease. Together with ALG8-CDG, it is the only known N-linked CDG without or with only minor neurologic involvement. Symptoms started between 1 month and 11 months of age and consisted of various combinations of recurrent vomiting, abdominal pain, protein-losing enteropathy, recurrent thromboses, gastrointestinal bleeding, liver disease and symptoms of hypoglycemia. Several patients have died (7).

The defect is in the first step in the biosynthesis of the nucleotide sugar GDP-mannose. The substrate of the enzyme, fructose 6-phosphate, does not accumulate because it is an intermediate of the glycolytic pathway. The blood biochemical abnormalities are indistinguishable from those found in PMM2-CDG. The diagnosis is confirmed by finding a decreased activity of phosphomannose isomerase (PMI) in leukocytes or fibroblasts or mutations in the MPI gene.

This is the only known CDG that is efficiently treatable. The treatment is simple and consists of oral mannose (1 g/kg body weight per day, divided in 4–6 doses). The rationale for this treatment is that hexokinases phosphorylate mannose to mannose 6-phosphate, thus bypassing the defect. Inheritance of MPI-CDG is autosomal recessive.

### 94.2.3 ALG6-CDG (Glucosyltransferase I Deficiency)

This is the second most common protein N-glycosylation disease (approximately 50 patients identified or known). As in PMM2-CDG, patients show hypotonia, strabismus, and seizures, but psychomotor development is less retarded, there is less dysmorphism, and usually, there is no retinitis pigmentosa or cerebellar hypoplasia. Long-term outcome is unknown because most reported patients have been children (8).

Glucosyltransferase I deficiency is a defect in the attachment of the first glucose (of three) to the dolichol-linked  $\text{Man}_9\text{-GlcNAc}_2$  ER intermediate. It causes hypoglycosylation of serum glycoproteins because non-glycosylated oligosaccharides are a suboptimal substrate for the oligosaccharyltransferase. For an unknown reason, some of the glycoproteins have unusually low blood

levels (particularly factor XI, and coagulation inhibitors such as antithrombin and protein C). The reason why the clinical picture in these patients is much milder than that of PMM-deficient patients may be because a deficiency in glucosylation of the dolichol-linked oligosaccharides does not affect the biosynthesis of GDP-mannose and, hence, does not affect the biosynthesis of GDP-fucose or the biosynthesis of glycosylphosphatidylinositol-anchored glycoproteins.

This disease illustrates that even in cases of mild psychomotor retardation without any specific dysmorphism, IEF of serum sialotransferrins has to be performed. When a type 1 pattern is found, PMM2 and PMI deficiency have to be considered first. If these enzymes show normal activities, the next step is analysis of the dolichol-linked oligosaccharides in fibroblasts. In ALG6-CDG, the major fraction of these oligosaccharides consists of nine mannose and two N-acetylglucosamine residues without the normally present three glucose residues. Glucosyltransferase I activity has to be measured in fibroblasts and/or mutation analysis performed.

No efficient treatment is available.

Inheritance is autosomal recessive.

### 94.2.4 ALG1-CDG (Mannosyltransferase I Deficiency)

The 10 reported patients showed epilepsy, severe psychomotor retardation, and a number of variable features such as fetal growth retardation, microcephaly, feeding difficulties, hypotonia, facial dysmorphism, liver dysfunction, cardiomyopathy, nephrotic syndrome, hypogonadism, abnormal visual evoked potentials, cerebellar hypoplasia, cortical atrophy, and depletion of  $\beta$  cells (9).

Lipid-linked oligosaccharide analysis showed an accumulation of  $\text{GlcNAc}_2\text{-PP-Dol}$  in the patients' fibroblasts.

No efficient treatment is available.

Inheritance is autosomal recessive.

### 94.2.5 RFT1-CDG (Flippase of $\text{MAN}_5\text{GLCNAC}_2\text{-PP-DOL}$ Deficiency)

This is a defect in the flippase that transfers  $\text{Man}_5\text{-GlcNAc}_2\text{-PP-Dol}$  from the cytoplasmic to the luminal side of the ER. The six reported patients showed a severe neurological syndrome with pronounced psychomotor retardation, important hypotonia, drug-resistant epilepsy, and sensorineural deafness (10). This is the first CDG showing deafness as a consistent feature.

Dolichol-linked oligosaccharide synthesis showed an accumulation of the aforementioned intermediate in fibroblasts.

No efficient treatment is available.

Inheritance is autosomal recessive.

### 94.2.6 MGAT2-CDG (N-Acetylglucosaminyltransferase II Deficiency)

Four patients have been reported with this first-identified N-glycan processing defect. Besides neurologic involvement (e.g. psychomotor retardation, epilepsy, behavioral disturbances), they presented with craniofacial dysmorphism, skeletal abnormalities, gastrointestinal disturbances, and growth retardation (11).
